³Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Diagnosis

The key concept underlying the diagnoses of attention deficit/hyperactivity disorder (ADHD) and hyperkinetic disorder (HKD) is that of maladaptively high levels of inattention, overactivity, and impulsiveness. These problems occur in different combinations in different individuals, and with different levels and types of associated problems. They are descriptions of behavior, not explanations.

Presentations, therefore, vary a great deal. A “classical” presentation would be of the full picture without other problems. A child presents because of disorganized behavior in which *inattention* describes a lack of attention to detail, a short attention span in un motivating situations, forgetfulness, distractibility in situations requiring focus on a task, and a slapdash attitude. *Overactivity* describes an excess of movement in situations requiring calm, such as the classroom, family meals, or visits to church or relatives. *Impulsiveness* refers to action without reflection, so affected people are accident-prone, impatient, intrusive on the activities of other people, and hasty (and therefore inept) in making decisions.

The results are manifold. Difficulties in personal relationships, school achievement, discipline, and emotional life can all appear (see section “Longitudinal Course”). Clinical presentations are, therefore, with a wide range of difficulties, and one of the clinical skills required is to recognize the ADHD pattern underlying the surface presentation.

Historical evolution of the concept

The prehistory of ADHD is the formulations of mental disorder in childhood that stressed lack of control and wildly disruptive behavior and presumed roots in the individual's constitution (Crichton, 1798; Haslam, 1809). The idea developed into “a defective organization in those parts of the body which are occupied by the moral faculties of the mind” (Rush, 1812). George

Frederick Still (1902) described disorders of “moral control,” in which aggressive, defiant, and overemotional conduct was attributed to constitutional failures of inhibitory volition. With hindsight, this is often claimed as a first description of ADHD; and indeed problems in sustaining attention were included in Still's descriptions; but there is no evidence from contemporary citations that he influenced other clinical scholars before the 1970s. Rather, a neurological tradition described “hyperkinetic syndrome” or “Kramer-Pollnow syndrome” (Neumärker, 2005), and a “minimal brain damage” (MBD) syndrome, so that hyperactive behavior became part of the picture of the “brain-injured child” (Strauss & Lehtinen, 1947). The idea of MBD was largely abandoned as it became clear that there was no unique syndrome of brain damage and that it was not legitimate to infer brain damage on the basis of hyperactive (or other) symptomatology alone (Rutter *et al.*, 1970).

The idea of a syndrome in which activity and attention problems were central may be attributable in part to the rise of medication. Early trials of amphetamines described the outcomes as better school performance and relaxation (Bradley, 1937; Cutler *et al.*, 1940; Bender & Cottington, 1942); as the description of drug effects became more refined, overactivity and inattentiveness took over as key outcomes (Eisenberg *et al.*, 1963). Emotional over-reactiveness was often included in descriptions of minimal brain dysfunction (e.g., Clements, 1966), until the very influential DSM-III codified the key problems as inattentiveness (IA), hyperactivity (HA) and impulsiveness (Imp).

Diagnostic schemes

Current differences between schemes reflect the disparate historical origins of the concept. DSM-IIIR, -IV, -IV(TM), and DSM-5 have tweaked the criteria of DSM-III, but maintained a tradition of description based on adding the criteria that are met, and applying a cut-off validated by the scores of young people who have been diagnosed in US practice. ICD-9 and ICD-10

have relied rather on providing a description of the condition, as a prototype to which clinicians fit cases on the basis of symptom pattern. ICD-10 calls the condition “HKD,” requires the combination of IA and HA-Imp, and has strict requirements for pervasiveness of symptoms. The result is that HKD is a subtype nested within ADHD, accounting for about a quarter of cases, and characterized by more neurodevelopmental alterations in motor and language development than other forms of ADHD (Taylor *et al.*, 1991), a more marked response to methylphenidate compared with placebo (Taylor *et al.*, 1987), and a less satisfactory response to behavioral treatment than to medication (Santosh *et al.*, 2005). HKD does not, however, seem to be a separate condition, either genetically or in course over time.

It is clear that the defining behaviors cluster together; a systematic review and meta-analysis concluded that their association with each other is indeed strong enough to sustain ADHD as a valid concept (National Institute for Health and Care Excellence (NICE), 2009). It is less clear how their structure is best described.

Dimensions, categories, and subtypes

Dimensions

Parent and teacher rating scales have found that levels of hyperactivity and inattentiveness are continuously distributed in the population, without any sign of a discontinuity at the extreme (e.g., Taylor *et al.*, 1991). Factor analytic studies have (of course) found dimensions. An innovative approach has come from the comparison of different types of factor structure. Toplak *et al.* (2009) contrasted two models of confirmatory factor analysis and two bifactor models, all applied to the same data set of parent and self-report interviews for adolescents. The best fit came from allowing both a unitary component across all ADHD symptoms and two distinct factors of inattention and hyperactivity-impulsivity.

The separation of dimensions of inattentiveness and overactive impulsiveness has clinical and scientific value. A systematic review and meta-analysis of 546 studies by Willcutt *et al.* (2012) concludes that there is “overwhelming” support for the distinction, not only from the internal, statistical correlations of symptoms, but also from stability over time, and the differential prediction of external associations. HA-Imp predicts selectively to aggression, rejection by peers and accidents; IA to poor academic function, shy and passive social behavior in children, and lower life satisfaction in adults. The distinction is not absolute; the dimensions are correlated with each other; but they deserve separate attention in clinical assessment. The correlation between inattentiveness and impulsiveness can mostly be attributed to their having genetic influences in common (McLoughlin *et al.*, 2007).

A dimensional way of thinking allows the balance of components to be assessed, and related problems brought in. As instance, emotional lability and irritability are very common features—and were part of the diagnosis until DSM-III removed them as criteria—but carry extra implications about clinical

profile and family history (Sobanski *et al.*, 2010) and should contribute to a diagnostic formulation.

Categories and subtypes

By contrast with the validity of dimensions, the categorical subtypes of DSM-IV—predominantly inattentive, predominantly hyperactive, and combined—have fared less well. They show only modest differences between themselves, and they are unstable over time (Lahey & Willcutt, 2010). Such differences as there are do not suggest that the DSM-IV subtypes add any extra predictive validity to that which is achieved by dimensions. The DSM-5 downgrades them from “subtypes” to “presentations”.

The weakness of the subtypes may come—not from the absence of categorical dysfunctions in nature—but from poor operational definition. A “predominantly inattentive” subtype, for instance, is defined partly by having fewer than six symptoms of hyperactivity-impulsiveness (American Psychiatric Association, 2000). Five symptoms, however, still imply a substantial load of impulsive behavior. Many children characterized as predominantly inattentive might more realistically be seen as showing a mild form of a combined subtype. Some studies, based on questionnaire ratings rather than DSM criteria, have identified a group of inattentive children with a more rigorously defined absence of impulsive or hyperactive features—for instance, scoring less than one standard deviation above the population mean (Taylor *et al.*, 1991; Warner-Rogers *et al.*, 2000). This “restrictive inattentive” type is not disruptive or aggressive. Indeed, affected children may be dreamy and rather inert, but muddled, disorganized, and impersistent in the classroom. They often show neurocognitive problems, but of a rather mixed kind, including working memory problems, poor spatial skills, language delay, poor motor coordination, and even (but not necessarily) a low IQ. Such a group has not found its way into the DSM-5 or ICD-10 classifications, because of a lack of adequate scientific study.

There are practical advantages to a category of ADHD (see Chapter 2). It helps clinicians who must make binary decisions such as whether or not to refer or to medicate, and it helps people who suffer from the condition, their families, and the public at large to understand the nature of the condition. Most clinicians in most countries will find it useful to use a mixture of categorical and dimensional approaches. The first step in assessment will probably be to define the presence or absence of ADHD; but a fuller analysis should quantify the levels of severity of inattentiveness and hyperactivity/impulsivity separately—together with the levels of associated problems, functional impairment, impact on others, other strengths and weaknesses (e.g., athletic ability), peer acceptance, and risk, as indicated in Chapter 32.

Clinical assessment

A range of screening questionnaires is available (see Chapter 33). Some were developed to monitor response to therapy

(e.g., Conners' Teacher and Parent Rating Scales) and subsequently refined statistically (Conners, 2008). (Modifications, such as the IOWA Conners, selected items from the most relevant subscales). Some other scales came from an epidemiological tradition (e.g., the Strengths and Difficulties Questionnaire (SDQ), which modified the Rutter A(2) and B(2) Scales (Goodman, 1997) and the longer Child Behavior Problems Checklist (Achenbach & Edelbrock, 1983)). Other scales were developed from DSM-III or DSM-IV criteria, such as the ADHD Rating Scale (DuPaul, 1991), the Vanderbilt Rating Scale (Wolraich *et al.*, 2003), and the SNAP-IV scale (Swanson *et al.*, 2005). Others again were developed for specific purposes, for example, to describe the range of behaviors that can occur in different situations (Barkley, 1991).

Many of these rating scales have similar strengths and weaknesses. Test-retest reliability is typically around 0.7; most give a discrimination between cases and controls at around two standard deviations, separating the means of ADHD and control populations; all are sensitive to the effects of medication. Free access from the internet is available for the SNAP-IV and SWAN (www.adhd.net) and the SDQ (www.sdqinfo.org). Most consist of items, reflecting DSM descriptions, each of which is scored for intensity (e.g., SNAP, DBD, Conners) or frequency (Vanderbilt, DuPaul [as above]), which are then summed to give a dimensional score. The distribution of scores on most scales is far from normal: there is a J-shaped distribution with a great excess of cases at the lowest levels. One consequence is that the scales are not suitable for parametric analyses (though often submitted to them); another is that a cut-off score based on a standard deviation criterion will identify more cases than may be intended. The SWAN scale was therefore developed with a wider range of scores for each item (e.g., "far above average" as well as "far below average") to yield a more Gaussian distribution (Swanson *et al.*, 2005). It is likely to be helpful in describing the full range in the population. All scales, used as a population screen, are liable to overidentify cases at the extreme. The questionnaires are best seen as a first stage of screening, not as defining casehood.

Indeed, screening in the general population is not yet established as a valuable clinical procedure (e.g., Tymms & Merrell, 2006). The limitations of population screening are likely to include not only an overidentification of cases, but also harmful effects of identification on stigma and teachers' expectations; a lack of community agencies to respond to screen-positive cases; and the risk that impaired children who are not detected will go without service.

Referral to services

Prevalence estimates in many countries outside the United States (see later, *Epidemiology* section) make it plain that most cases of ADHD are never diagnosed. In the United Kingdom, most parents do discuss their concerns with education services, but this does not lead to referral even to primary health care (Sayal *et al.*, 2006). For those parents who do seek help from

primary care, much depends on their health literacy. If they complain of hyperactivity, an appropriate referral follows; if their complaint is of behavior or learning problems in general terms, then hyperactivity, impulsiveness, and inattention are not diagnosed even if present (Sayal *et al.*, 2002). A systematic screen, applied selectively for children with problems presenting to primary health care and remedial education services—using the rating scales described above—is therefore a promising way of improving recognition, and assisting specialist referral, in countries where recognition is incomplete.

At mental health and pediatric services, the course of assessment will follow the outline of Chapter 32. Parental interview, report from teachers, and examination and observation of child are the recommended means of eliciting behavior. Multiple informants are useful because affected children will still vary across contexts. Research interviews are systematic and encourage comprehensive coverage, but are usually too lengthy and focused to be feasible in clinical practice. It remains important to ask for details of behavior in specific situations rather than for generalized ratings of problems (such as "impulsiveness"), which are vulnerable to imperfect knowledge of what is typical.

Problems and pitfalls in diagnosis

Cut-offs

The continuous distribution of ADHD symptoms in the population makes for uncertainty about where to place the division between normal variation and psychopathology. For research purposes, where replicability is key, it is sensible to follow the international conventions: at least six out of the nine inattentiveness criteria, and/or at least six out of nine hyperactive-impulsive. These remain the standard for childhood and adolescent diagnosis in DSM-5.

For clinical purposes, however, an unintelligent addition of criteria is not always best. For instance, a child with five out of nine inattentiveness criteria and five out of nine hyperactive-impulsive does not get an ADHD diagnosis, while one with no inattentiveness and six out of nine hyperactive-impulsive does receive a diagnosis (HA-IMP presentation)—in spite of a lower load of ADHD symptoms.

Developmental appropriateness

Symptoms need to be considered in the light of what is appropriate to different ages and levels of development. "Hyperactivity," for example, may be a whirlwind in the preschool period, fidgetiness in adolescence, and subjective restlessness in adulthood. Diagnosticians need to build up sufficient experience of attention and activity at different ages, both in typically developing children and in differing forms of psychopathology, that they can recognize when a child's attention and activity are deviating from what is expected. Indeed, this should be an important aspect of professional training. A short cut is to accept the judgment of other professionals, especially experienced teachers, about what is atypical. There will, however, be times when those judgments

are misleading—for example, are colored by the rater's relationship with the child.

Misdiagnosis is particularly easy for children with intellectual disability (see Chapter 54). The diagnosis can be missed by attributing all the problems to a low IQ, or overrecognized by treating the cognitive problems of intellectual disability as evidence for ADHD. There are two styles of coping with this problem: the first is to refer the child's level of difficulty to that of others at similar levels of intellectual delay. This distributional approach, however, risks overlooking the probability that ADHD features are *disproportionately* common in people with immature brains. A second approach is to refer the child's level of difficulty to those of ordinary children whose chronological age corresponds to the developmental age of the child being assessed.

Diagnosis in adult life

Inattention and impulsiveness often persist into adult life; some people are not diagnosed in childhood; therefore some people will present for the first time as adults. The number of DSM symptoms tends to diminish, but impairment persists (and DSM-5 requires 5 rather than 6 symptoms to be present).

Self-report can be more accurate than in childhood, but the report of people who know the person well remains crucially important. Furthermore, evidence about childhood status needs to be sought—from parents, siblings, school reports, and a reconstruction of biography. It is rare for ADHD features to appear for the first time in adulthood, and when they do, they suggest other psychopathology such as substance misuse, early dementia, mania, or encephalopathy. Diagnosis therefore requires evidence of ADHD symptoms in childhood – but not necessarily of impairment from them. The retrospective dating of onset is often imprecise, and DSM-5 therefore requires only the presence of symptoms before the age of 12 years.

Sources of information: conflicts

If there is disagreement between sources, the diagnostician should make a judgment about the reasons. Perhaps an inexperienced parent is making ratings without knowledge of what to expect from children, or in a way that is colored by their relationship. Perhaps a teacher is overstating problems in order to obtain help for the child, or understating because of fear that the child may be medicated. Alternatively, the problem behaviors may indeed be situation-specific, directing attention to the qualities of the situation, including domestic conflict or inappropriate school expectations.

Differential diagnosis

The presence of ADHD or HKD should be recognized even in the presence of other psychiatric conditions. Some conditions, however, may masquerade as ADHD by reproducing some of its features.

Other forms of overactivity can be distinguished. Manic overactivity is goal-directed, rather than the disorganized pattern

of ADHD. Children in the spectrum of autism may show a driven, stereotyped pattern of overactivity that can be extreme and worsened by anti-hyperactivity medication. Children with multiple tics may appear to show impulsive overactivity until it is appreciated—sometimes by prolonged observation—that the activity level is composed solely of a large number of sudden, repetitive movements.

Other forms of inattentiveness can also be separated. Learning disorders may be accompanied by reluctance to engage in academic tasks, but (unlike that of ADHD) it is often specific to tasks that are unduly difficult for the individual.

Other forms of disruptive behavior may also need to be distinguished. Insomnia may produce an irritable child who is not engaging in classroom activity, but (unlike ADHD) it is accompanied by daytime sleepiness, and the problems do not disappear when the insomnia is relieved. Oppositional behavior alone may be responsible for a child's appearance of not listening and task refusal, and in young children it can be hard to distinguish from impulsive behavior, so the absence of inattention is a helpful guide when the problem is oppositionality without ADHD.

Other forms of emotional dysregulation need consideration. Emotional dysregulation is also a feature of bipolar disorder. The ADHD pattern is distinguished from bipolar in that it is not episodic but a persisting trait, and by the absence of the euphoria and grandiosity that characterize the episodes of mania (see Chapter 62).

All these conditions that can masquerade as ADHD may also be coexistent with ADHD. The key for the diagnostician is, therefore, to discern whether the disorganized pattern of ADHD behavior is also present, and to make the additional diagnosis (or diagnoses) as necessary.

This process of differential diagnosis is to be distinguished from the confusion that may come from a different etiology. Brain syndromes, such as fragile-X or tuberous sclerosis may well be responsible for ADHD features. Both the neurological condition and the ADHD should then be recognized. More subtly, severe neglect in early childhood is probably a cause of attention and activity abnormalities (see section "Risk Factors"), and if ADHD is present in such a child, then it should still be diagnosed. A social worker identifying a neglect syndrome and a physician diagnosing ADHD in the same child may both be right.

Coexistent disorders

Other neurodevelopmental phenotypes are frequently present. Autism spectrum conditions, for example, affect about one-third of children with diagnosed ADHD (Reiersen *et al.*, 2007). Twin studies suggest that about half of the genetic influences are common to both disorders (Ronald *et al.*, 2008). Motor problems, specific learning difficulties, and tics are also common (and see Chapter 3).

Disruptive mood dysregulation disorder, in which a persisting trait of dysphoric and irritable mood is accompanied by extreme outbursts of temper or aggression, is usually accompanied by

dyscontrol of activity and attention. It is therefore better seen as a coexistent, rather than as a differential disorder: the question for formulation is not either/or but which component should be tackled first.

Oppositional and conduct problems, anxiety and social immaturity often emerge in the course of development (see section “Longitudinal Course”). When oppositional and conduct problems are present together with ADHD, then the ADHD is likely to have come first; the ADHD carries the same implications of neurocognitive delays and responsiveness to stimulant drugs as does ADHD alone; and genetic influences inferred from twin studies are for the most part common to both (Taylor, 2010). A variant of the gene coding for catechol-*o*-methyl transferase (COMT) is associated only with the combined condition, not with either ADHD or conduct problems alone, which could imply that the combined condition is genetically partially distinct (Caspi, 2008). Nevertheless, for clinical purposes, one can proceed on the basis that ADHD functions as a risk factor for the development of conduct problems, and can be treated separately.

Epidemiology

Prevalence

ADHD is remarkable for the great disparity in rates of given diagnosis in different parts of the world. Estimates gathered by Hinshaw *et al.* (2011) of children who were medicated because of ADHD varied from around 60 per 1000 school-age children in the United States, through 10–30 per 1000 in Canada, to 3 per 1000 in the United Kingdom and less than 1 in Brazil and China. Estimates from other surveys suggested 9 per 1000 in Germany and 1.8 per 1000 in France (Taylor, 2013).

Figures for the rates of diagnoses, as given in practice, are not usually gathered systematically, and are often hard to interpret, but the picture is one of marked variation by country. Even within the United States, administrative prevalence rates vary greatly with the Centers for Disease Control and Prevention (2010) reporting rates varying from 62/1000 (in California) to 156/1000 (North Carolina) on the basis of parents reporting whether their child had ever received the diagnosis. Skounti *et al.* (2007) summarized results of 39 community surveys from various countries (1992–2005); the reported rates for school-age children varied from 22 to 178 per 1000. The highest rates came from the United States, Spain, and Germany, and from studies based on single-source ratings (e.g., teacher only).

Polanczyk *et al.* (2007) made a systematic review of all prevalence studies reporting rates of DSM or ICD diagnoses for people under the age of 18. Worldwide, the average rate was 53/1000; it varied greatly (from 10 to 190/1000) but the main reasons for variation were in the diagnostic criteria used, the source of information used, and whether impairment was included in the criteria. Geographical differences, after allowing for the above,

were minor and only significant in discriminating between North America on the one hand and Africa and the Middle East on the other. In one set of studies, comparing 7-year-olds in London, England and Hong Kong, the “local” definition—based on questionnaires from teachers and parents—yielded a much higher prevalence in Hong Kong; while the “international” definition—based on interviews and tests—yielded a somewhat higher prevalence in London (Luk, 1996).

The implication is that cultures vary only a little in the true prevalence of activity and attention problems—but vary greatly in the impact that these problems have on the concerns of adults who know the children and are responsible for their welfare. Correspondingly, the rates of children diagnosed in practice have been rising in most countries: in the United States, from 78 per 1000 in 2003 to 95/1000 in 2007 (Centers for Disease Control and Prevention, 2010). At both points, rates were higher when the family’s primary language was English, or when they had Medicaid cover for health care. The gender ratio was 2.8:1.

Risk factors

ADHD risk is made up of many interacting genetic and environmental factors, and is mediated by multiple brain networks—with different individuals affected in different ways and at different times and to different degrees by these factors. There is good evidence for ADHD dimensionality and against the notion that there is a causal discontinuity when one reaches pathological levels of inattention and impulsiveness (review by Coghill & Sonuga-Barke (2012)). A developmental perspective is necessary. Figure 55.1 gives a simplified picture of multiple early influences (genetic and prenatal) interacting with later (genetic and social and physical environmental) risk and protective processes to create a spectrum of disease liability.

Genetic influences

It is pretty clear that genetic influences are involved. The strongest evidence comes from studies comparing the similarity of monozygotic and dizygotic twins: genetic influences account for 70–90% of the variance in different studies, on the (reasonable) assumption that environmental factors influence both twins more or less equally. Data from research has not, however, established an unequivocally causative role for individual genetic variants (Thapar *et al.*, 2012). Several molecular genetic variants are known to be associated, but their effects are small and the causal pathways are not established.

Some of the best evidence for specific genetic influences comes from recent findings of an increased rate of *de novo* and inherited chromosomal deletions and/or local duplications (so-called copy number variants—CNVs) in ADHD (Williams *et al.*, 2010; Williams *et al.*, 2012). The sites involved appear diverse, but different genes may converge on shared biological processes (Stergiakouli *et al.*, 2012).

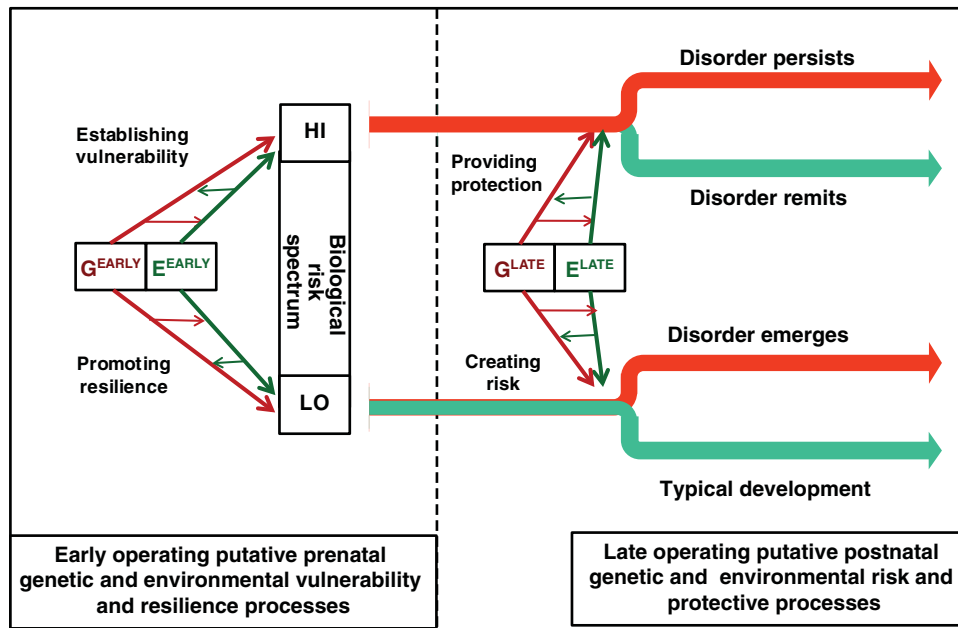

Figure 55.1 ADHD pathogenesis: developmental psychopathology schematic showing the way that early and late operating risks act together to determine continuities and discontinuities in disorder paths.

Meta-analysis of candidate gene studies has established associations with genes regulating brain neurochemistry, especially in the dopamine (DA) system (e.g., D4 and the dopamine transporter (DAT1); Faraone *et al.*, 2005) and other neuromodulator systems such as serotonin and norepinephrine; Oades *et al.*, 2008). Linkage studies have not found replicable disease susceptibility loci for ADHD (Arcos-Burgos *et al.*, 2004). Hypothesis-free genome-wide association studies, which tag a very large number of markers of common genetic variants in very large samples, have confirmed an overall genetic contribution to ADHD (Stergiakouli *et al.*, 2012) but have so far failed to identify genome-wide substantial effects for individual markers. To date, therefore, most of the heritability is unexplained. Five of the best established genetic variants—serotonin 1b receptor, serotonin transporter, DA D4 and D5 receptors, and the DAT—have been estimated to account for only 3.2% of the variance in symptoms of ADHD, and 4.2% of the heritability (Kuntsi *et al.*, 2006). The advice given to families should still be that genetic influences are strong. The risk of ADHD occurring in other first-degree family members (such as brothers and sisters) is raised about fivefold. Nevertheless, the scientific difficulty in specifying the precise influences responsible makes genetic counseling inexact for affected families. We only recommend investigation of chromosomes and DNA for individual patients when there are specific reasons—such as a phenotype suggesting a large gene effect (e.g., Williams syndrome), or the presence of many affected family members, or the existence of other neurodevelopmental problems (e.g., intellectual disability) that are enough in themselves to indicate genetic evaluation (see Chapter 54).

Environmental influences

Genetic and environmental influences are profoundly intertwined for ADHD and need to be considered jointly (see Chapter 24). Several, potentially harmful factors in the early environment are reliably associated with ADHD, but none is unequivocally established as a cause (Thapar *et al.*, 2012). The developmental pathways involved can be complex. Genetic factors can influence both the exposure to environmental risks (G–E correlation) and the susceptibility of the individual to them (G–E interaction; see Chapter 24).

Prenatal associations include maternal smoking during pregnancy (in contrast, see Thapar *et al.*, 2009), maternal alcohol consumption, and use of non-prescribed drugs of abuse, prescribed drugs such as anticonvulsants and anxiolytics, maternal stress, and maternal hypothyroidism.

Perinatal associations include low birth weight, prematurity, and obstetric complications.

In postnatal life, associations include an inadequate diet, iodine deficiency and major B vitamin deficiencies, iron and lead poisoning, high exposure to industrially contaminated areas, old paint, and soft-water areas where lead water pipes are common.

Some artificial food colorings and preservatives have been implicated as risk factors by contrasting them with inert substances in a community-based randomized double-blind trial (McCann *et al.*, 2007): as a consequence the implicated coloring has been regulated in the UK and Europe. Exposure to insecticides, such as dichlorodiphenyltrichloroethane (DDT), has been implicated in animal models but has not been confirmed clinically (Mariussen & Fonnum, 2006).

Social environmental effects include exposure to extremely depriving institutional environments (Stevens *et al.*, 2008). More ordinary variations in family environment may also be implicated as influences on developmental course rather than initiating factors. ADHD elicits negative, intrusive, and harsh responses from parents, which then influence the later emergence of comorbid social and emotional problems (Taylor *et al.*, 1996).

Various medical illnesses are also risks for the development of poor concentration, irritable mood, and problems of conduct. In young children, eczema and sleep problems are common reasons for the upsets, and successful treatments of these primary problems will often relieve the mental problems too (see Chapter 70).

A narrow disease model of ADHD has led to genetic factors typically being thought of as operating in a rather fixed way across the lifespan. By contrast, our developmental model of ADHD pathogenesis makes a distinction between early and late operating genetic effects (see Figure 55.1). Greven *et al.* (2011) demonstrated, using longitudinal twin data, that patterns of stability and change in ADHD symptoms were the result of both stable genetic influences and newly appearing influences emerging at different points across the life span. Environmental influences too need to be appraised in relation to their timing. There is, for instance, evidence from the English Romanian Adoptees study that at least 6 months institutional deprivation is required before the risk of ADHD rises, while later catch-up can be achieved for many deprived children once exposed to normal family environments (Stevens *et al.*, 2008).

Clinical implications

Knowledge of risks has advanced to the point where it can inform advice to patients and their families. The understanding that there are genetic influences often comes as a liberation from personal guilt. Parents are vulnerable to societal views that their parenting failures have produced the features of ADHD, and can be freed by good advice to use their problem-solving and coping skills. It is also important to avoid any impression that genetic influences imply an unalterable course. Parents and teachers can have a major influence for good on their children's ability to cope with ADHD.

Parents have sometimes been led to give undue weight to single events in the history. Minor obstetric complications are seldom "the cause," any more than minor infractions of health advice in pregnancy (such as low levels of alcohol intake). In many countries, there is a public view that broad social factors are responsible—for instance, rises in television viewing or internet use. It is therefore worth noting that shared environmental factors appear to play very little part.

Prevention programs, however, do not yet have a comprehensive rationale. It certainly makes sense for clinicians to support good services for maternal health in pregnancy and to include mental health in that remit; to know their community's

exposure to lead or deficiency in iodine and include screening for their effects when it is cost-effective; to support nutrition programs (including psychological enrichment); to detect and refer learning difficulties when they are present; and to end exposure to depriving institutional care; but none of these desirable approaches rely solely on ADHD risk for their justification (see Chapter 3).

Pathogenesis

ADHD and brain structure

Structural alterations in multiple brain systems have been implicated in ADHD (Sonuga-Barke & Fairchild, 2012). Group comparisons with controls find significantly smaller brains in ADHD (Castellanos *et al.*, 2002) with cerebellum, corpus callosum, striatal—for example, caudate nucleus, putamen and globus pallidus (Ellison-Wright *et al.*, 2008) – and frontal regions—for example, dorso-lateral prefrontal cortex (DLPFC) (Valera *et al.*, 2007) – especially affected. Reduced thickness of cortex, especially DLPFC, is evident (Batty *et al.*, 2010). There is also evidence of altered patterns of cortical folding—effects perhaps related to early environmental influences (Wolosin *et al.*, 2009). Diffusion tensor imaging suggests alterations in white matter integrity in a range of key fiber pathways thought to subserve cognitive functions implicated in ADHD (van Ewijk *et al.*, 2012). Key regions in the reward and emotion processing networks such as the ventral striatum and the amygdala may also be implicated (Plessen *et al.*, 2006).

The few studies that have examined developmental changes in brain structure have demonstrated a degree of continuity in ADHD effects (Castellanos *et al.*, 2002). Recent analyses have supported the notion of a delayed developmental trajectory in ADHD rather than a fixed deficit. Remission of symptoms is associated in some studies with a relative normalization of brain structure and function (Shaw *et al.*, 2010).

ADHD and brain chemistry

The hypothesis that ADHD is based on dopamine (DA) dysregulation is supported by genetic, imaging, and pharmacological studies (Oades *et al.*, 2005). Positron emission tomographic studies have produced mixed results with some supporting the view that ADHD is associated with low tonic levels of DA, with phasic levels varying according to task demands (reviewed by Prince, 2008). This is supported by the clinical observation that some DA agonists (e.g., methylphenidate, amphetamine) reduce ADHD symptoms, probably through an increase of extracellular DA (Pliszka, 2005). DA neurons innervate the brain networks (see below) implicated in ADHD deficits. A DA hypothesis is further supported by the genetic studies implicating DA genes (see above) and by studies using animal models with pharmacological lesions and gene knockouts of

catecholamine systems (Madras *et al.*, 2005). It must however be added that other neurochemicals, such as norepinephrine and serotonin (Oades *et al.*, 2008), are implicated in ADHD, that some effective medications (e.g., imipramine) have little DA effect, and the interactions between neurotransmitters are complex (Olijslagers *et al.*, 2006).

ADHD and brain function

Brain function is altered in ADHD in multiple networks subserving a range of neuropsychological functions, often mapping on to the structural effects reported above. Simple models of ADHD as a disorder of executive function have been replaced by a model of pathophysiological heterogeneity.

Executive function is altered in several domains (Willcutt *et al.*, 2005), especially in inhibitory-based interference control processes (Barkley, 1997) and in working memory (Rapport *et al.*, 2008), but also in planning and attentional flexibility (Willcutt *et al.*, 2005). Functional imaging studies provide evidence to suggest that inhibitory-based deficits are linked to hypoactivation in prefrontal cortex (Rubia *et al.*, 2005) and the dorsal striatum (Vaidya *et al.*, 2005).

Altered motivational and reward-related processes are also implicated in ADHD. Functional magnetic resonance imaging (fMRI) studies implicate hypoactivation in the ventral striatum/nucleus accumbens and the orbito-frontal cortex in response to cues of anticipated rewards (e.g., Plichta *et al.*, 2009). One of the most consistent findings in this domain is that ADHD individuals respond differently to delayed reward (e.g., Marco *et al.*, 2009). This may be due to altered signaling of future rewards and higher rate of decay of the value of those rewards as suggested in models by Sagvolden *et al.* (2005). Alternatively, it has been suggested that ADHD is associated with delay aversion (a negative affective state induced by delay cues and imposition) and that escape from delay is a primary motivator for ADHD behavior (Sonuga-Barke *et al.*, 2010).

A third network attracting increasing attention in ADHD research is the so-called default mode network. This is one of a number of resting state networks centered on the mid-line structures—the medial prefrontal cortex and the posterior cingulate cortex/precuneus, which in optimal conditions are active during rest and deactivate during the transition to task performance (Raichle & Snyder, 2007). During rest, these regions are important for introspective thought and self-awareness but persistence or emergence of activity within this network during task performance is associated with intra-individual variability and intermittent errors thought to reflect attentional lapses. This network shows reduced connectivity in ADHD during rest (Fair *et al.*, 2010) and reduced attenuation during rest-to-task transitions: both effects that can be normalized with stimulant medication (e.g., Liddle *et al.*, 2011).

The research on reward and delay has highlighted the context-dependent nature of ADHD deficits. An alternative perspective on this issue is provided by the state regulation

model. This is based on the cognitive energetic framework of Saunders which integrates energetic factors such as arousal, activation, and effort into information processing. According to this model ADHD children are hypothesized to have particular difficulties in regulating their psycho-physiological state during periods of under- or over-activation/arousal and are therefore less capable of effectively allocating effort to regulate suboptimal states (Sergeant, 2005).

ADHD is probably not a single neurobiological entity but rather an umbrella term covering a range of different pathophysiological profiles. Each deficit (i.e., executive, reward/delay, default mode, and cognitive-energetic) affects only a minority of cases. In one recent study, distinctive groups of ADHD were affected selectively by either executive function problems, delay aversion, or timing problems (Sonuga-Barke *et al.*, 2010). Psychological changes may map on to development: Halperin *et al.* (2008) found that patients who showed a persistent pattern of disorder between childhood and adolescence could be distinguished from those who remitted on the basis of the integrity of their executive or effortful control processes, a finding which the authors argue is consistent with the idea that recovery from ADHD is associated with emergence of well-functioning executive control functions. The frequency of brain changes in people with ADHD, and their continuity over time, have contributed to the reclassification in DSM-5 of ADHD as a “neurodevelopmental disorder”; see Chapter 3.

Longitudinal course

Referral for ADHD is most common in middle childhood when the symptoms of ADHD, their neuropsychological correlates, and associated clinical features start to impact negatively on everyday function across a range of psychological domains and social and educational arenas (von Stauffenberg & Campbell, 2007). Because of this, the 8-year-old boy struggling to work alone at school, disruptive at home, and experiencing difficulty making friends because of his overbearing and reactive style of interaction is in many minds the ADHD archetype. Longitudinal studies, however, make clear that these patterns of impairment nearly always have their roots early on in the preschool period (Sonuga-Barke & Halperin, 2010) and very often persist across the life span in one form or another (Biederman *et al.*, 2012).

Preschool

Accounts of ADHD in the preschool period highlight the early emergence of extreme overactivity, noncompliance, and a tendency to temper outbursts linked to emotion dysregulation, in children with already established temperamental reactivity (Campbell *et al.*, 2000). This early behavioral pattern is usually already linked with a range of neuropsychological deficits and intellectual delay (Schoemaker *et al.*, 2012). The existence in ADHD preschoolers of social and pragmatic language problems

may make the differential early diagnosis of autism challenging (Mandell *et al.*, 2007). These impairment patterns can be compounded by parenting that is disorganized and ineffective within chaotic family environments, sometimes reflecting genetic similarity of parent and child (Mokrova *et al.*, 2010). This early appearing constellation of ADHD-related features may be described as risk markers or a prodromal state of the later clinical condition. Psychometric studies, however, suggest that the ADHD diagnosis has validity and utility by the age of 3 or 4 (Riddle *et al.*, 2013). At this age, the predominantly hyperactive/impulsive subtype is more prevalent than the inattentive subtype—probably because evidence of attention deficits is not so apparent in the contexts in which infants and young children operate (Lahey *et al.*, 2005).

Middle childhood

Community-based and longitudinal studies highlight symptomatic and diagnostic continuity between preschool and school (e.g., Lee *et al.*, 2008). Children meeting the criteria for ADHD in preschool are likely to go on to have ADHD in middle childhood, while many new cases are diagnosed. School entry may be seen as the first major life transition of particular significance for children with ADHD. Children diagnosed after this will rarely be true *de novo* cases, but more likely cases where histories of subclinical symptoms and/or impairment are exacerbated by the new challenges in the academic and social environment and associated increased demands for self-regulation and effective attention management (Sonuga-Barke *et al.*, 2005). Failure to adapt to this new and challenging environment may lead children with ADHD to fall behind in their studies, and get into trouble at school and at home (Lahey & Willcutt, 2010). There can be great difficulty creating and maintaining strong and positive relationships outside the home (Mrug *et al.*, 2002). At the same time, coercive cycles of interaction with parents and siblings within the home often develop (Lifford *et al.*, 2009). Typical patterns of comorbidity, especially aggression and non-compliance, become more apparent during these middle-child years (Kadesjö & Gillberg, 2003).

Adolescence

The next major pinch point in the ADHD life journey occurs during the transition from childhood to adolescence. Once again longitudinal study suggests strong continuities between these two developmental periods with the persistence of disorder in the majority of cases (Barkley *et al.*, 1990). The disorder seems to be especially persistent in children with comorbid conduct problems. While overall levels of overt hyperactivity may start to recede, impulsiveness and inattention continue to constrain adolescent adjustment and healthy development (Willoughby, 2003). There is a risk of low self-esteem and distorted self concept, perhaps a product of dysfunctional family and peer relationships and school and social failure in childhood; and these can lead on to low mood and feeling of worthlessness (Drabick *et al.*, 2006; Edbom *et al.*, 2006).

Educational underachievement is common and the risk for the emergence of delinquency and early onset substance use disorder is increased (Molina & Pelham, 2003). ADHD may increase the risk of suicidal ideation and behaviors during adolescence, especially where there are co-occurring mood disorders (Chromis-Tuscano *et al.*, 2010).

Adult life

The next crucial developmental transition is from adolescence to adulthood. Once again continuities in disorder are evident, but levels of overt ADHD symptoms appear to reduce further, often replaced by feelings of internal agitation and restlessness that in turn further the risks of anxiety and depression (Adler, 2004). Levels of impairment across a range of outcomes and reduced quality of life remain stubbornly problematic, especially in the case where ADHD in childhood was accompanied by conduct problems (Kessler *et al.*, 2006).

Adulthood brings new challenges and new opportunities for people with ADHD. There is an increased need for self-organization, in budgeting, paying bills on time, remembering appointments, finding lost objects, maintaining personal appearance, and meeting deadlines. In personal relationships, good timing is no less important; and calmness in the face of provocation is often needed in many kinds of personal and business negotiations. Impulsive decision making can have worse consequences than in childhood, with more opportunity to destroy one's life through risky behavior. All these can make inattention and impulsiveness more handicapping than they were in childhood, and are responsible for some apparently *de novo* presentations.

On the other hand, adulthood brings more opportunities for managing one's life. Choice of career may take one into walks of life where rapid changes of activity are necessary and valued (e.g., sales, trading, and some kinds of performing arts). Delegation of routine and tedious tasks may be possible in teams; a partner may take over some of the organizational tasks of everyday life. An increasing capacity to understand one's condition brings the possibility of a happier relationship to it.

Heterogeneity

While it is helpful to think of ADHD as having a characteristic developmental phenotype that can be charted across the life span, the idea that there is a single trajectory runs counter to what we know of the complexity of ADHD developmental psychopathology (as illustrated in Figure 55.1) and the heterogeneity within disorders (see Chapter 3). Multiple ADHD developmental phenotypes exist, each marked by different temporal patterns of symptoms and impairment, leading to different ages of onset, persistence, acceleration, elaboration, and adjustment—and, for some, recovery. Some children may have an early onset and severe form which accelerates during middle childhood to become associated with substantial comorbidity during adolescence but remits as the person enters adulthood. For others, ADHD problems may be later in onset

but persist long into adult life. Although little is currently known about the genetic and environmental factors and underlying neurobiological processes that might shape these different developmental pathways, there are some interesting examples of environmental buffering from the literature (Sonuga-Barke & Halperin, 2010). For instance, parental responsiveness and tolerance, perhaps promoted by parent-focused interventions, may protect against the development of conduct problems in children with ADHD (Taylor, 1999). Actual (through remission) or functional (through the development of coping) recovery is perhaps more common than we might suspect and a study of the factors that would predict such an optimal outcome is urgently required.

Treatment

Treatment should begin with careful and responsive advice and explanation (see “Clinical Implications”). Extended courses of “psychoeducation” can have beneficial effects on parental ratings of hyperactivity (Ferrin & Taylor, 2011) as well as on their intended target of assisting people to cope with the problems imposed.

Specific treatments have been widely researched and reviewed. Drug trials especially provide a substantial evidence base. National guidelines generally agree on the forms of intervention that should be used, and that both psychological and pharmacological therapies should be available (Seixas *et al.*, 2012), but differ on the important question of indications. North American guidelines suggest either that both forms of treatment should be used, according to clinical judgment (American Academy of Child and Adolescent Psychiatry, 2007); or that medication is primary, with psychosocial interventions an important adjunct (American Academy of Pediatrics, 2011). By contrast, guidelines for England, Wales, and Northern Ireland (NICE, 2009), Scotland (Scottish Intercollegiate Guidelines Network, 2009), and Europe (Taylor *et al.*, 2004) give priority to psychosocial interventions (especially parent training) in all but severe cases, with medication as a second line of intervention.

The differences between countries arise for several reasons, partly cultural and partly professional. Prendergast *et al.* (1988) compared the practices of US and UK clinicians in diagnosing the same bank of case vignettes and videotapes: in comorbid cases, the US clinicians gave priority to the component of ADHD, the British to that of oppositionality and conduct problems.

Medication

Central nervous stimulants (methylphenidate, dexamfetamine and lisdexamfetamine) and atomoxetine are licensed in many countries. Bupropion, guanfacine, clonidine, and modafinil are also in widespread use as alternative antihyperkinetics, in spite of not being approved in Europe. Some preparations

of methylphenidate are available in North America, but not widely elsewhere—for instance, a transdermal preparation and a dextro-enantiomer. Chapter 43 summarizes the pharmacology of the main drugs available, their dose ranges and durations of action, and their legal status.

Central nervous stimulants

CNS stimulants are usually the first choice of medication, and methylphenidate is usually the first choice of stimulant. Dexamfetamine is at least as powerful—probably more so—but its safety is less well established. The prodrug lisdexamfetamine has been recently introduced (and may have advantages related to its longer duration of action).

All show beneficial effects in reducing parent-, teacher-, and self-ratings of hyperactive, impulsive and inattentive behaviors. Effect sizes are, in general, large (meta-analysis by Banaschewski *et al.*, 2006). Quality of life ratings also tend to improve; many tests of cognitive function show changes toward becoming more normal; no tests of cognitive function are known to deteriorate. With careful attention to administration and monitoring, the majority of treated children should reach a good level of social function.

Safety

Adverse effects can also occur. Serious adverse effects are rare in trials (Aagaard & Hansen, 2011). This might underestimate the hazards in real life, but a review of adverse effects, from surveillance programs as well as trials, has come to a similar conclusion—that adverse effects are for the most part minor, readily managed symptomatically, and do not persist when the drug is stopped (Graham *et al.*, 2011). Table 55.1 indicates recommended monitoring, symptomatic management, and “second-line” actions when the problems do not resolve or are severe.

The rare, severe problems that can be encountered in practice are not necessarily the result of medication, and referral to an appropriate specialist is usually appropriate. Increases in blood pressure are considered hazardous when they exceed the 95th centile for the population, corrected for age and sex, and should lead to immediate dose reduction or discontinuation. Further management should be between cardiology and psychiatry, preferably with psychiatry leading. Most alternative medications are just as likely as the stimulants to cause raised blood pressure, so the choice for persisting hypertension will be between dose reduction or discontinuation and the addition of clonidine (or guanfacine) which tend to lower the blood pressure. The choice will depend largely on the severity and impact of the ADHD itself.

Arrhythmias, or risky changes in the electrocardiogram (ECG), will naturally call for a cardiological evaluation before treatment. Indeed, some authorities recommend ECG evaluation for all children before beginning therapy, as would be the case for imipramine (which is effective for ADHD, but not included in these recommendations because of its

Table 55.1 Management of adverse effects of medication.

	Monitoring	Symptomatic	Second line
Appetite loss and growth reduction	Growth charts	Altering intake through day. Modifying times of doses. Dose reduction. Drug holiday	Alternate antihyperkinetics or nondrug therapy
	Parent report Pre- and post-medication	Altering dose regime (either reducing or increasing evening cover)	Replace with Atomoxetine
Sleep problems		Sleep hygiene Melatonin	Alternative antihyperkinetics or agreed nondrug therapy
	Blood pressure increase	Dose reduction Clonidine	24-hour recording Specialist referral if over 95th centile
Tachycardia	Pretreatment history and examination	ECG evaluation Dose reduction	Specialist referral
	Measurement when BP recorded		
Substance misuse	Tablet count	Psychoeducation	Replace with Atomoxetine
	Enquiry at psychiatric review	Motivational interview	
Mood change	Psychiatric review	Consider alternative antihyperkinetic	Add Fluoxetine or mood stabilizer

potential for cardiotoxicity). For stimulants and atomoxetine, however—which do not prolong conduction times—the purpose would be to detect the presence of a congenitally prolonged Q-Tc interval and therefore a risk that an arrhythmia might be precipitated if the heart rate were increased by the drug. In our view, the frequency of this congenital anomaly (approximately 1 in 2000 children) is not great enough to make a routine ECG cost-effective. Rather, there should be a clinical evaluation before treatment to detect any suspicion of cardiac problems—including a history of undue breathlessness or syncope on exertion, a cardiac murmur on examination, or a family history of sudden death in young family members—with ECG if risk factors are present.

Substance misuse figures strongly in the worries of families about drug treatment. The stimulants are controlled drugs, and can be misused to obtain euphoria if they are taken intravenously or by inhalation. In these circumstances the drug should be stopped at once and permanently. Oral administration, however, does not lead to euphoria. Absorption from the gut leads to a much slower onset and offset of DA increase in the striatum, by comparison with the addictive drugs that increase DA, such as cocaine (Volkow *et al.*, 2001). Extended-release preparations (such as Oros-methylphenidate and lisdexamfetamine) are very hard to abuse, since they do not support rapid increases in blood level.

While misuse for recreation is rare, diversion by selling or giving tablets to others is not uncommon. The main current misuse is by students who do not have ADHD but value the

effects of stimulants in improving concentration on study and counteracting fatigue. Modafinil has a similar niche. Cognitive enhancement such as this raises issues for society at large, about the acceptability of such attempts at self-improvement by people without disorders.

Supposed risks have sometimes been given scare coverage by the media and in the professional press. The risk for sudden cardiac death is probably no higher than in the general population—though it is so rare that millions of treated cases will be needed to rule out the possibility completely—and such data are being accumulated in current research (Graham *et al.*, 2011). Brain damage has not been found: MRI suggests that those who have been given stimulants, by comparison with unmedicated ADHD, show a more normal pattern of age-related maturation (Nakao *et al.*, 2011). Cancer, in the Danish National Registries, was not associated with use of stimulants (Steinhausen & Helenius, 2013).

Dosage

Chapter 43 provides the usual range of doses but individuals vary in their requirements both for overall quantity and for timing of doses. Prescription begins at the lower end of the range, and builds up (e.g., by 10 mg daily each week) to the level giving optimal combination of benefits and adverse effects. Some young people require, and can take safely, doses above the normal range. Where there is only a small response, and no adverse effects have appeared, then doses up to the equivalent of 100 mg of methylphenidate in a day have been

regarded as reasonable by NICE (2009) but require careful monitoring.

Immediate-release versus extended-release treatment

In the initial phase of dosage adjustment, immediate-release stimulants allow for frequent adjustments of timing and dose. This does however assume the possibility of close monitoring with adequate professional time and good cooperation (e.g., from teachers). Furthermore, the transfer to extended-release may not be straightforward. When close titration is not possible, then we advise using extended-release treatments from the start and adjusting dose (and, if necessary, preparation) to give the best profile of action through the day—taking into account the desirability of monitoring action into the evening to allow for satisfactory family relationships and successful homework, yet of not interfering with sleep.

In the longer term, meta-analytic comparison of those taking immediate-release with extended-release preparations does not suggest major superiority for one or the other (Punja *et al.*, 2013). Limited evidence favors long-acting for parent ratings, quick-acting for teacher ratings (Banaschewski *et al.*, 2006). This could indicate the extent to which parent ratings are driven by behavior in the evenings, and the risk that prescribers relying solely on parent reports may go to higher dose levels than is optimal for school. Teachers may then be concerned that children are over-treated and lacking in spontaneity.

Atomoxetine

Atomoxetine is also an effective drug. Its beneficial effects are similar to those of the stimulants (reviewed by Hanwella *et al.*, 2011), but the time course of action is longer. The effect size is somewhat smaller than for methylphenidate in meta-analyses of controlled trials (Banaschewski *et al.*, 2006), but it may be underestimated because of the restricted length of most trials. The manufacturers indicate that the full effects may take 6–8 weeks to appear, but clinical experience suggests that it may take longer and there may still be improvements up to 12 weeks. This prolonged process of establishing effect can have both strengths and weaknesses: some families will give up prematurely if the early changes are insufficiently striking. On the other hand, there are benefits for some in a medication whose effects do not fluctuate greatly during the day.

Adverse effects over the longer term are in general similar to those of the stimulants (Hanwella *et al.*, 2011). Suicidal thinking emerged as a complication from reviews of the trial data, and families should be warned of the need to take seriously and report any expression of self-destructive thoughts. The drug is however much less likely than the stimulants to cause insomnia; it reduces rather than increases tics; it does not give rise to euphoria and is not a controlled drug. It may well be the first choice of medication when those additional problems are present or expected. It is still effective in cases which do not respond to stimulants, and is regarded as the best approach in

those cases. It can then be given together with methylphenidate for the transitional period while its effect is building up.

Nonpharmacological therapies

Given the current limitations of, and constraints on, pharmacological treatments, the availability of effective nonpharmacological treatments is imperative. These may involve psychological therapies and/or dietary modifications. Their value as distinct from pharmacological approaches is especially important for those patients and/or practitioners who are resistant to the use of medicines for ADHD. The use of psychological and dietary treatments has been advocated as part of multimodel packages (Taylor *et al.*, 2004), with these recommendations based on published reviews (Arns *et al.*, 2009; Fabiano *et al.*, 2009; Bloch & Qawasmi, 2011; Nigg *et al.*, 2012).

Dietary interventions involve both supplements to address putative deficiencies (minerals, vitamins, and fatty acids) and exclusions (of artificial food colors and preservatives; or a wider range of foods to which children may be idiosyncratically intolerant). They are not specific to ADHD and they are described more fully in Chapter 43.

Psychological interventions are also various. Parent training is the most commonly employed. It comes in a range of different forms (see Chapter 37) and some are recommended for use with ADHD children specifically (Thompson *et al.*, 2009; Webster-Stratton *et al.*, 2011). Modifications for ADHD may include psycho-educational modules about the nature of the condition (Montoya *et al.*, 2011); and/or an increased focus on the clarity and directness of communication (e.g., eye contact and short and clear messages) (Sonuga-Barke *et al.*, 2001). In some cases parent training is integrated with school-focused approaches employing teachers (Sayal *et al.*, 2012). A number have a special focus on improving the parent-child relationship and emphasis on increasing enjoyment in interactions (Griggs & Mikami, 2011).

More recently, parenting approaches have started to include elements that aim to strengthen self-regulatory abilities thought to be deficient in children with ADHD in the form of specific games and tasks (Halperin & Healey, 2011). They are recommended for ADHD children through middle childhood, and thought to be especially valuable for preschool children (Halperin *et al.*, 2012). Specific behavioral approaches can be valuable in targeting particular areas of difficulty such as social relationships (Corkum *et al.*, 2010) and organizational skills (Abikoff *et al.*, 2012). With some adaptation, they can be useful in adolescence (Sibley *et al.*, 2012). In adolescence and adulthood, approaches incorporate elements of cognitive behavior therapy to help support functional, and reduce dysfunctional, responses to daily social and practical challenges, increase problem solving, and develop self-control (Safren, 2006).

Other nonpharmacological approaches that might be valuable include intensive computerized training of attention, inhibition, and working memory, and neurofeedback. Computerized

training approaches typically work on the principle that underlying deficits in brain networks and associated cognitive processes can be remediated by structured exposure to repeated cognitive tasks in which task difficulty is continuously titrated so as to challenge but not overwhelm an individual's abilities (Klingberg *et al.*, 2005). Packages often require extended treatment programs before improvements can be seen and therefore require a significant investment from families. A range of different neurofeedback packages are available—these employ adaptive reward-based techniques using brain visualization to improve attention via cortical self-regulation (Arns *et al.*, 2009).

For many of these psychological approaches there are insufficient well designed trials published to allow one to say whether they represent empirically-based treatments for ADHD, but isolated trials have provided positive results. A recent meta-analysis of randomized controlled trials challenged the existing evidence for the efficacy of some of these treatments (Sonuga-Barke *et al.*, 2013). The investigation, which was confined to studies at ages 3–18 years in ADHD populations and using ADHD outcomes, separated outcomes into those made by people close to the intervention (e.g., parents delivering treatment) and those made by blinded investigators—either direct observations or made by raters (e.g., teachers) working in different settings from those where the intervention was made. Dietary interventions in general seemed to be helpful even when the probably blinded outcome was considered—although the effects were modest. For diets eliminating artificial colors and additives, the effect size (which in all cases was the standardized mean difference (SMD) between treated groups and controls) was 0.32 for the “open” raters, 0.42 for the “blind.” For diets eliminating a wider range of foodstuffs (usually, but not invariably, those suggested by individual testing for intolerance), the SMD calculation for the “open” raters was difficult to interpret because of great heterogeneity among studies. “Blind” ratings yielded a 0.51 SMD (but with wide confidence intervals and not statistically significant). Essential fatty acid supplements (e.g., fish oil to provide omega-3 polyunsaturated fatty acids), gave SMDs for “open” raters of 0.21, and for “blind” 0.16.

The psychological treatments gave a rather different picture. For cognitive training procedures, such as working memory training and attention training, SMD for “open” raters was 0.64, for “blind” raters 0.24. For neurofeedback the relevant figures were 0.59 for the most proximal raters and 0.29 for the “blind.” For behavioral interventions, (typically parent- or teacher-mediated training to increase desired /reduce undesired behaviors) SMD for “open” raters was 0.40, which dropped dramatically to 0.02 for probably blinded ratings. In summary, statistical significance was found in a wide variety of therapies. The effect sizes, however, are rather small by comparison with those of drugs. Furthermore, for the psychological interventions they are critically dependent upon using outcomes provided by people who are aware that the child received the active therapy and were often heavily invested in its delivery and outcomes.

In the meta-analyses described above, only the elimination of artificial colorings and giving of fish oil had statistically significant effects upon blinded outcomes; the effect of the latter intervention was modest or very small.

The NICE and EAGG recommendation—for parent training to be the front line for most children—could therefore be seen as overstating the case. The NICE analysis did concur in finding much smaller effects of parent training on teacher ratings than on parent ratings. This could reflect an inflated estimate of change at home resulting from nonblind raters. It could, however, also represent a problem of generalization from home to school rather than a failure to have an effect; and blind raters during direct observation in the home might be insensitive to real therapeutic actions. Even if the effects were only on short term and localized to changes in parental perception, they could still prove to be valuable—especially for situations where the ADHD problems are specifically intra-familial. If they lead to more generally sympathetic rearing environments in the longer term, this could cut the risk of the development of comorbid disorders such as ODD and anxiety/depression. The effects of the interventions on ODD and other comorbidities, or on parental behavior and expectations, were not studied in these meta-analyses.

The challenge for the future is to bring our growing knowledge of the pathophysiological basis of ADHD to the process of therapeutic innovation to allow us to develop more effective nonpharmacological treatments for the benefit of patients and their families. Given the somewhat disappointing nature of some of these results, it has been suggested that efforts relating to non-pharmacological treatments for ADHD should be focused on the development of early identification and intervention in the preschool period when the disorder and its underlying causes may be more amenable to environmental influence (Halperin *et al.*, 2012).

Choice of initial treatment approaches

Both pharmacological and psychological approaches should be available for children and their families, and clinicians should be able to give advice about diet and exercise. Medication is more efficacious than psychological approaches, but carries some physical hazards. The decision about whether to begin with either or both needs to be made on an individual basis. It would be useful to be able to predict which children will do better with which treatment approach. A randomized, 14-month comparison of behavioral and medication approaches favored the latter (The MTA Cooperative Group, 1999). Intensive medication was superior to intensive behavior therapy in reducing core ADHD features, and behavior therapy added little to medication. Longer term follow-up yielded a different emphasis: improvements were maintained, but there seemed to be no superiority of any of the intensive treatments—either to each other or to routine community treatment (Molina *et al.*, 2009). One should note that the later outcome came after both randomization and intensive interventions had ended. The apparent equivalence

of treatments probably reflected both the ending of intensive therapeutic efforts after the 14-month outcome, and the effectiveness of self-selection of individual families for the treatment approach that suited them best. Both possibilities emphasize the importance of including families in the choice of therapy.

Individual prediction of drug responsiveness from laboratory measures has not been very powerful—certainly less informative than a short medication trial (Ferrin & Taylor, 2011). A reanalysis of the MTA study, however, did suggest that children meeting the ICD-10 criteria for 'HKD' showed a much greater superiority, of intensive medication to intensive behavioral work, than was the case for other children with milder levels of ADHD symptoms (Santosh *et al.*, 2005). The most severely affected children are also the most likely to benefit from the help of medication.

Treatment of refractory cases

Some children will fail to respond even to a combination of behaviorally oriented parent training and trials of stimulants and atomoxetine. The reasons for poor response should then be

analyzed (see Figure 55.2). Sometimes the standard treatment has not been optimally delivered and is worth a more strenuously supervised trial. Sometimes the persisting problems are the comorbid features and need managing in their own right. Sometimes the case features of impulsiveness, overactivity, and inattention have not responded to full standard therapy, and will require a more intensive and specialist approach, such as higher doses of standard drugs, off-label use of alternative antihyperkinetic drugs (see Chapter 43), management of side-effects that have limited the therapy (Table 55.1), or intensive behavioral work with child or family. Sometimes a full assessment of drugs is needed, even requiring in-patient admission.

Treatment in comorbidity

Figure 55.2 includes some actions to be taken when other problems are present. For the most part, the treatment of the ADHD itself is unaltered, albeit with particular attention in monitoring to avoid worsening the coexistent condition. For children with autism and other neurological problems, dosage titration may need to be frequent, and primarily against

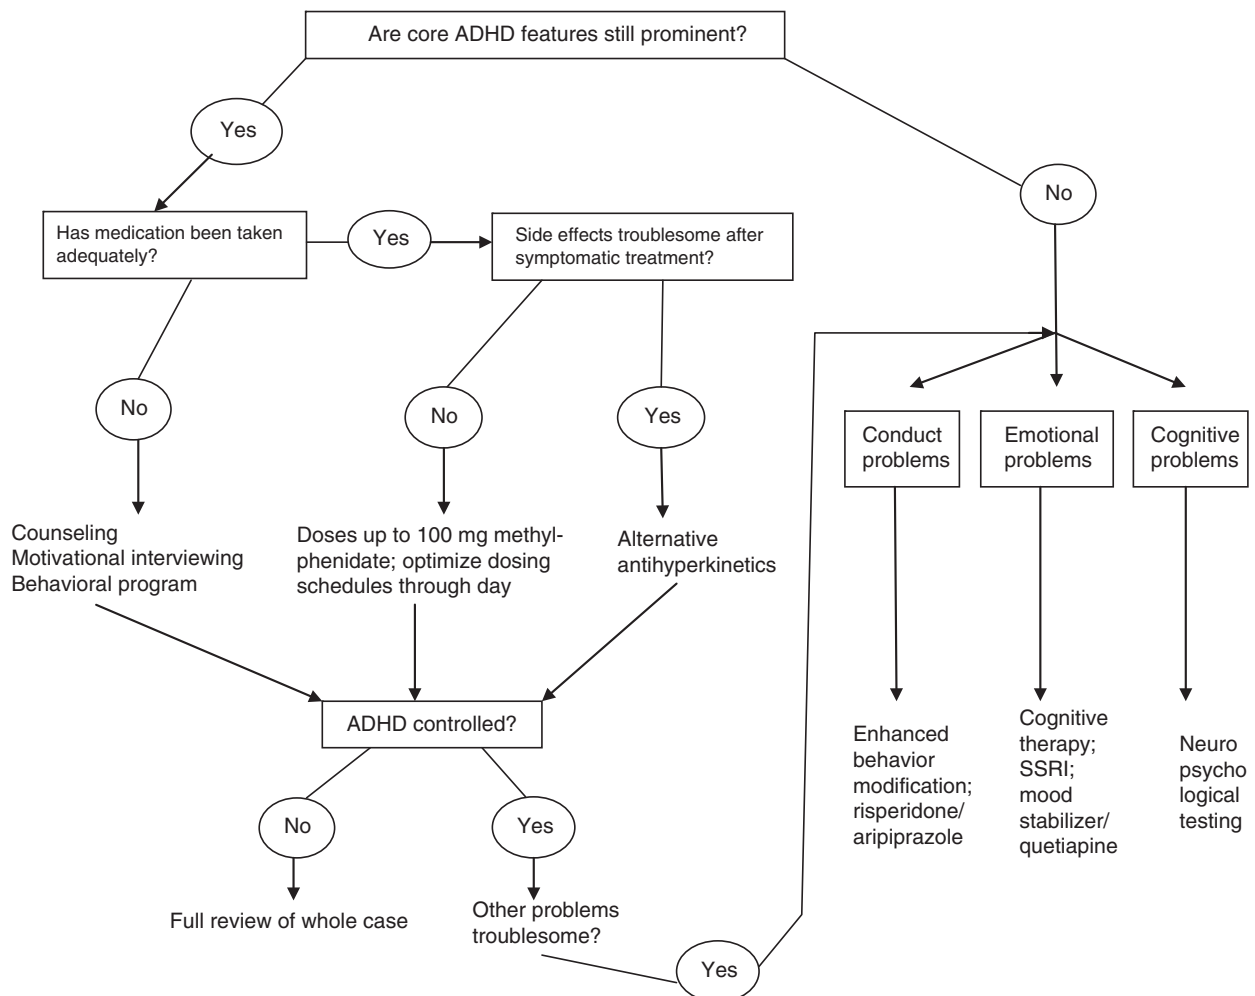

Figure 55.2 Poor response to standard therapy.

adverse effects (see Chapter 51). Substance misuse presents particular difficulties. Occasional cannabis use is not necessarily a contraindication to stimulants—there seem to be few interactions—but addicted patients with ADHD need to be managed by someone expert in both. Stimulant and other drugs may well help the ADHD, but should not be expected to be effective for established substance misuse.

Long-term treatment

ADHD is a risk for later mental health and for health problems such as accidents. A systematic review by Shaw *et al.* (2012) has found evidence for adverse outcomes being more common in ADHD than in unaffected people, and less common in those who have been treated than for people with ADHD who have not.

There have now been enough trials of treatment in adults to be confident that medication is still effective, and that cognitively based therapies and learning coping skills are promising; a systematic review is provided by the Canadian Agency for Drugs and Technologies in Health (2011). It is less clear what degree of continuation of therapy is needed. There is a little evidence that adults with continuing symptoms make a better adjustment if their ADHD is controlled with medication. Lichtenstein *et al.* (2012), for instance, find less offending during periods of medication than in periods of abstinence.

In the absence of definitive evidence, an individualized approach is recommended. Periodic periods off medication (e.g., 2 weeks every 2 years) will make it clear whether a drug is still desirable. (There should still be an option for returning to medication subsequently if necessary.) Patients should become increasingly knowledgeable about medication effects through their adolescence. Most do so and become intelligent consumers (Singh *et al.*, 2005). Existential questions are raised by the power of the therapies, and patients are often taxed to understand whether their 'real self' is that with ADHD or that when ADHD is controlled. The consequences include decision making about whether to take the medication at all—or only when environmental demands for attention and self-control are high. Responsive discussion with a knowledgeable professional is greatly valued by most people with ADHD, who share with other forms of disability the need to make a balance between overcoming its continuing problems and living within the limitations that it imposes.

CHAPTER 56

Tic disorders

James F. Leckman^{1,2} and Michael H. Bloch²

¹ Child Study Center and the Departments of Psychiatry, Pediatrics and Psychology, Yale University, New Haven, CT, USA

² Child Study Center and the Department of Psychiatry, Yale University, New Haven, CT, USA

Introduction

Tic disorders are transient or chronic conditions associated with difficulties in self-esteem, family life, social acceptance, or school or job performance that are directly related to the presence of motor and/or phonic tics. Although tic symptoms have been reported since antiquity, systematic study of individuals with tic disorders dates only from the 19th century with the reports of Itard (1825) and Gilles de la Tourette (1885). Gilles de la Tourette described nine cases characterized by motor “incoordinations” or tics, “inarticulate shouts accompanied by articulated words with echolalia [automatic repetition of words or made by another person] and coprolalia [sudden vocalization of obscene or socially inappropriate speech].” In addition to identifying the cardinal features of severe tic disorders, his report noted an association between tic disorders and obsessive-compulsive (OC) symptoms, as well as the hereditary nature of the syndrome in some families.

In addition to tics, individuals with tic disorders may present with a broad array of behavioral difficulties, including disinhibited speech or conduct, impulsivity, distractibility, motoric hyperactivity, and obsessive compulsive symptoms (Leckman *et al.*, 2013). Scientific opinion has been divided on how broadly to conceive the spectrum of maladaptive behaviors associated with Tourette’s syndrome (TS) (Shapiro *et al.*, 1988). This controversy is fueled in part by the frustration that parents and educators encounter when they attempt to divide an individual child’s repertoire of problem behaviors into those that are “Tourette-related” and those that are not. Population-based epidemiological studies and family-genetic studies have begun to clarify these issues, but much work remains to be done.

In this chapter, a presentation of the phenomenology and classification of tic disorders precedes a review of the etiology, neurobiological substrates, assessment, and management of these conditions. The general perspective that will be presented is that

TS and related disorders are associated with multiple genetic and environmental (epigenetic) mechanisms that interact over the course of development to produce a distinctive range of complex syndromes of varying severity.

Phenomenology of tics and diagnosis of tic disorders

Phenomenology of tics

A *tic* is a sudden, repetitive movement, gesture, or utterance that typically mimics some aspect or fragment of normal behavior (Leckman *et al.*, 2013). Individual tics rarely last more than a second. Individual tics can occur singly or together in an orchestrated pattern. They vary in their intensity or forcefulness. Motor tics vary from simple abrupt movements such as eye blinking, head jerks, or shoulder shrugs to more complex, apparently purposive behaviors such as facial expressions or gestures of the arms or head. In extreme cases, these movements can be obscene (copropraxia) or self-injurious, for example, hitting or biting. Phonic or vocal tics can range from simple throat clearing sounds to more complex vocalizations and speech. In severe cases, coprolalia (obscene or socially unacceptable speech) is present.

By the age of 10 years, most individuals with tics are aware of premonitory urges that may either be experienced as a focal perception in a particular body region where the tic is about to occur (like an itch or a tickling sensation) or as a mental awareness (Leckman *et al.*, 1993). Most patients also report a fleeting sense of relief after a bout of tics has occurred. These premonitory and consummatory phenomena contribute to an individual’s sense that tics are a habitual, yet partially intentional, response to unpleasant stimuli. Indeed, most adolescent and adult subjects describe their tics as either “voluntary” or as having both voluntary and involuntary aspects. In contrast,

many young children are oblivious to their tics and experience them as wholly involuntary movements or sounds. Most tics can also be suppressed for brief periods of time. The warning given by premonitory urges may contribute to this phenomenon.

Clinicians characterize tics by their anatomical location, number, frequency, and duration. The intensity or “forcefulness” of the tic can also be an important characteristic. Finally, tics vary in terms of their “complexity.” Complexity usually refers to how simple or involved a movement or sound is, ranging from brief, meaningless, abrupt fragments (simple tics) to ones that are longer, more involved, and seemingly more goal-directed in character (complex tics). Each of these elements has been incorporated into clinician rating scales that have proved to be useful in monitoring tic severity (Leckman *et al.*, 1989).

Diagnostic categories

Diagnostic categories provide a common basis for discussion and are an essential tool in epidemiological and clinical research. Several widely used diagnostic classifications currently include sections on tic disorders. These include both the *Diagnostic and Statistical Manual—Fifth Edition (DSM-5)* classification system published by the American Psychiatric Association (2013), and the *International Classification of Disease and Related Health Problems—10th Revision (ICD-10)* criteria by the World Health Organization (1996). Although differences exist, these classification schemes are broadly congruent, with each containing three major categories: TS or its equivalent; persistent (chronic) motor or vocal tic disorder (CMT or CVT) or its equivalent; and transient tic disorder or its equivalent. However, the *ICD-10* and *DSM-5* diagnostic groupings suffer from uncertainties about how best to categorize conditions that potentially encompass a broad range of symptoms that wax and wane in severity. Since the current nosological boundaries are set by convention and clinical practice, they may not reflect true etiological differences.

Transient tic disorder

Almost invariably a disorder of childhood, transient tic disorder is usually characterized by one or more simple motor tics that wax and wane in severity over weeks to months. The anatomical distribution of these tics is usually confined to the eyes, face, neck, or upper extremities. Transient phonic tics, in the absence of motor tics, can also occur, though more rarely. The age of onset is typically 3–10 years. Boys are at greater risk. The initial presentation may be unnoticed. Family practitioners, pediatricians, allergists, and ophthalmologists are typically the first to see the child. Missed diagnoses are common, particularly as the symptoms may have completely disappeared by the time of the consultation.

Persistent (chronic) motor or vocal tic disorder

This chronic condition can be observed among children and adults. As with other tic disorders, this condition is characterized by a waxing and waning course and a broad range of symptom severity. Chronic simple and complex motor tics are

the most common manifestations. A majority of tics involve the eyes, face, head, neck, and upper extremities. Although some children may display other developmental difficulties such as attention deficit hyperactivity disorder (ADHD), the disorder is not incompatible with an otherwise normal course of childhood. This condition can also appear as a residual state, where a predictable repertoire of tic symptoms may be seen only during periods of heightened stress or fatigue.

Tourette’s syndrome (combined vocal and multiple motor tic disorder)

The most severe tic disorder is best known by the eponym, “Gilles de la Tourette’s Syndrome.” Typically the disorder begins in early childhood with transient bouts of simple motor tics such as eye blinking or head jerks. These tics may initially come and go, but eventually they become persistent and begin to have adverse effects on the child and the family. The repertoire of motor tics can be vast, incorporating virtually any voluntary movement by any portion of the body (Leckman *et al.*, 2013). Although some patients have a “rostral-caudal” progression of motor tics (head, neck, shoulders, arms, and torso), this course is not predictable. As the syndrome develops, complex motor tics may appear. Typically, they accompany simple motor tics. Often they have a “camouflaged” or purposive appearance, for example, brushing hair away from the face with an arm, and can only be distinguished as tics by their repetitive character. They can involve dystonic movements. In a small fraction of cases (<5%), complex motor tics have the potential to be self-injurious. These self-injurious symptoms may be relatively mild, for example, slapping or tapping, or quite dangerous, for example, punching one side of the face, biting a wrist or gouging eyes to the point of blindness. On average, phonic tics begin 1–2 years after the onset of motor symptoms and are usually simple in character, for example, throat clearing, grunting, and squeaks. More complex vocal symptoms such as echolalia (repeating another’s speech), palilalia (repeating one’s own speech), and coprolalia occur in a minority of cases. Other complex phonic symptoms include dramatic and abrupt changes in rhythm, rate, and volume of speech.

Epidemiology

Children are 5–12 times more likely to be identified as having a tic disorder than adults. As with other neurodevelopmental disorders, including autism and ADHD, boys are more commonly affected with tic behaviors than girls (see Chapter 3). However, the reported male–female ratio varies considerably from 1:1 to 10:1 across epidemiological studies (Scahill *et al.*, 2013). Once thought to be rare, current estimates of the prevalence of TS vary 100-fold, from 2.9 per 10,000 (Caine *et al.*, 1988) to 299 per 10,000 (Mason *et al.*, 1998). More recently, Khalifa and von Knorring (2003, 2005) studied a total population of 4479 Swedish children aged 7–15 years. Twenty-five were identified

as having TS, yielding a prevalence estimate of 5.6 per 1000 pupils. Similar findings have been reported in Denmark and China (Jin *et al.*, 2005; Kraft *et al.*, 2012). Methodological differences (parent-report vs direct observation in the classroom) and threshold differences (chronic motor disorder is much more common than a full case of TS) likely account for some of the reported variation in prevalence rates and possibly the male–female ratio estimates.

Clinical course

Motor and phonic tics tend to occur in bouts. Their frequency ranges from nonstop bursts that are virtually uncountable (>100 tics per minute) to rare events that occur only a few times a week (Peterson & Leckman, 1998). Single tics may occur in isolation, or there may be orchestrated combinations of motor and phonic tics that involve multiple muscle groups. The forcefulness of motor tics and the volume of phonic tics can also vary from behaviors that are not noticeable (a slight

shrug or a hushed guttural noise) to strenuous displays (arm thrusts or loud barking) that are frightening and exhausting. During periods of waxing tic symptoms, clinicians may find themselves under extreme pressure to intervene medically. While such interventions may be warranted, it is often the case that the tic symptoms will wane substantially within a few weeks (Figure 56.1).

By the age of ten, most children and adolescents have some awareness of the premonitory urges that frequently precede both motor and vocal tics (Leckman *et al.*, 1993; Woods *et al.*, 2005). These urges add to the subjective discomfort associated with having a tic disorder. They may also contribute to an individual's ability to suppress their tics for longer periods of time.

The factors that determine the degree of disability and handicap versus resiliency are largely unknown. They are likely to include the presence of additional developmental, mental, and behavioral disorders; the level of support and understanding from parents, peers, and educators; and the presence of special abilities (as in sports) or personal attributes (intelligence, social abilities, and personality traits). The behavioral and emotional

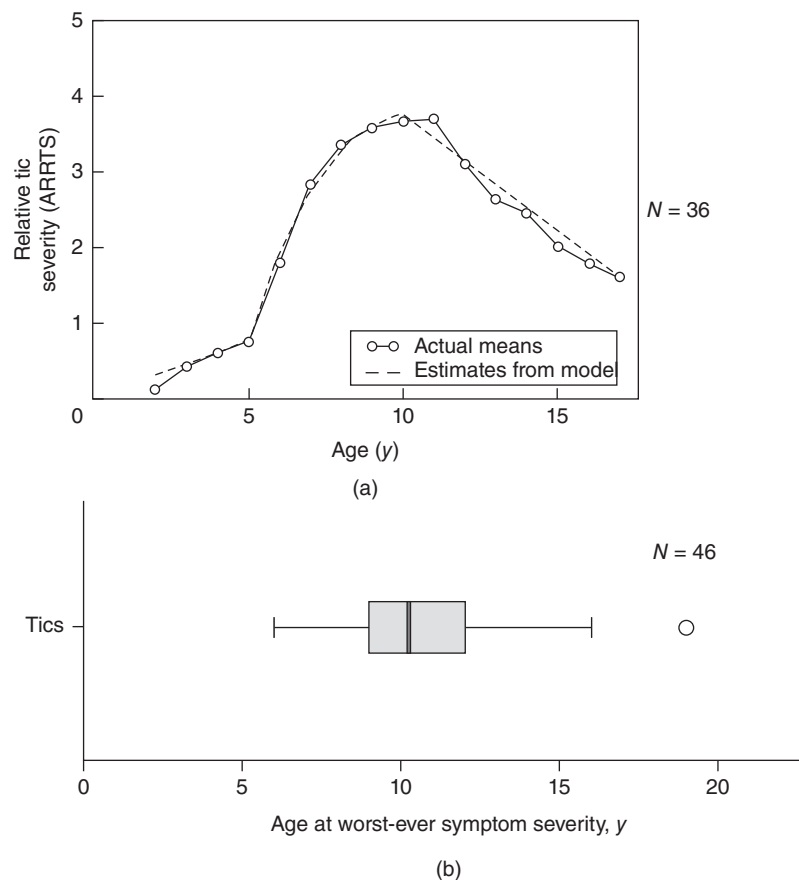

Figure 56.1 Course of tic severity. (a) Plot of average tic severity in a cohort of 36 individuals from ages 2–18 years. Tics typically have an onset between ages 4 and 6 years, reach their worst between ages 10 and 12 years, and then decline in severity throughout adolescence. In the ARRTS (Annual Rating of Relative Tic Severity), parents rate the tic symptoms of their children on a six-point ordinal scale (absent [0], least severe, mild, moderate, severe, and most severe [6]). (b) Box plot representing age when tic symptoms were at their worst. Age (years) is represented for all 46 subjects with Tourette's syndrome in a prospective longitudinal study (Bloch *et al.*, 2006). The mean \pm SD worst-ever tic severity score using the Yale Global Tic Severity Scale (0–50) was 31.6 ± 7.7 (range, 15–48) at a mean \pm SD age of 10.6 ± 2.6 years (range, 6–19 years). Source: Reproduced with permission of Wiley.

problems that frequently complicate TS range from impulsive, “disinhibited,” and immature behavior to compulsive touching or sniffing. At present, there are no clear dividing lines between these disruptive behaviors and complex tics on the one hand and comorbid conditions of ADHD and obsessive-compulsive disorder (OCD) on the other (Leckman *et al.*, 2013).

Although children with TS can be loving and affectionate, maintaining age-appropriate social skills is particularly difficult for many of them (Dykens *et al.*, 1990; Cath & Ludolph, 2013). Whether this is due to the stigmatizing effects of the tics, the patients’ own uneasiness, or some more fundamental difficulty linked to the neurobiology of this disorder is unknown.

Relatively few cross-sectional or longitudinal studies of tic disorders have been performed (Leckman *et al.*, 1998; Bloch *et al.*, 2006a). These studies indicate that tic disorders tend to improve in late adolescence and early adulthood (Bloch, 2013). In many instances, the phonic symptoms become increasingly rare or may disappear altogether, and the motor tics may be reduced in number and frequency. Complete remission of both motor and phonic symptoms has also been reported. In contrast, adulthood is also the period when the most severe and debilitating forms of tic disorder can be seen. The factors that influence the continuity of tic disorders from childhood to adolescence to adulthood are not well understood but likely involve the interaction of normal maturational processes occurring in the central nervous system (CNS) with the neurobiological mechanisms responsible for TS, the exposure to cocaine, other CNS stimulants, androgenic steroids, and the amount of emotional trauma and distress experienced by affected individuals during childhood and adolescence. In addition, tic disorders may be etiologically separable so that some of these factors, such as activation of the immune system or exposure to heat stress, may influence the clinical course for some individuals but not for others. Other factors, such as psychological stress often associated with the negative and stigmatizing interactions with others (parents, teachers, peers, and other people in the environment) who do not understand the involuntary nature of tics, may have a more uniform impact.

The natural history of TS has clear implications for the treatment of individuals with this condition. Children with tics have a substantial probability of improvement of their tic symptoms during adolescence and young adulthood. Given the ephemeral nature of tics in many children, pharmacological treatment should be conservative and focused on reducing functional impairment. Parents, teachers, and peers can benefit from psychoeducational interventions.

Clinical assessment

Assessment instruments

The complex motor, vocal, and behavioral phenotype of TS presents a unique challenge to measurement. Although the visible and audible nature of core TS symptoms allows direct

observation, their waxing and waning character, even over the course of the day, presents challenges to the clinician. A variety of clinician-, parent-, and self-report rating instruments are available for tics and associated symptoms, for use in clinical practice and/or research settings (Cavanna & Pansaon Piedad, 2013). The Yale Global Tic Severity Scale (YGTSS) is the most widely used measure of tic severity in TS and other tic disorders (Leckman *et al.*, 1989). It is based on a semistructured interview of symptoms over the past week, where the clinician is asked to document the patient’s motor and phonic tics. The motor and vocal tics are rated separately, based on their number, frequency, intensity, complexity, and interference from 0 (no tic symptoms) to 5 (severe). The tic severity subscore consists of the motor and phonic tic severity scores. This is added to the impairment subscore, which rates the severity of functional impairment from 0 to 50, to produce the total score (0–100). In addition to the YGTSS, the Premonitory Urge for Tics Scale (PUTS) is being increasingly used to characterize individuals with tic disorders. The PUTS is a relatively brief self-report scale designed to quantify the premonitory sensory urges that frequently precede motor and vocal tics (Woods *et al.*, 2005). The PUTS contains 10 descriptions of somatic sensations. The severity of these urges is rated on a 4-point ordinal scale ranging from 1 (not at all true) to 4 (very much true). A wide range of psychometrically validated clinician- and self-rated measures for OC, ADHD, depressive, and anxiety symptoms are also available (see Chapters 33, 55, 60, 61, and 63) and they are commonly used in assessing individuals with TS and other tic disorders. As noted in Chapter 33, the potential differences between information gathered from clinicians and patients should always be considered if the assessment is to be considered comprehensive and accurate.

Comorbid conditions

The past decade has seen a renewed emphasis on the range of neurological and psychiatric symptoms seen in patients with TS (Leckman & Cohen, 1998; Martino & Leckman, 2013). In both clinical and epidemiological samples TS alone is the exception rather than the rule (Khalifa & von Knorring, 2005, 2006; Scahill *et al.*, 2013). Symptoms associated with ADHD and OCD have received the most attention. It is also becoming clear that the more severe the tic disorder, the greater the likelihood of detecting coexisting conditions, even in representative, population-based samples (Scahill *et al.*, 2013).

Both clinical and epidemiological studies vary according to setting and established referral patterns, but it is not uncommon to see reports of 30–50% of children with TS diagnosed with comorbid ADHD (Khalifa & von Knorring, 2006). TS has the highest rate of ADHD relative to the other lesser variants of tic disorders. Although the etiological relationship between TS and ADHD is in dispute, it is clear that those individuals with both TS and ADHD are at a much greater risk for a variety of untoward outcomes (Dykens *et al.*, 1990; Carter *et al.*, 2000;

Peterson *et al.*, 2001; Sukhodolsky *et al.*, 2003, 2005). They are often regarded as less likeable, more aggressive, and more withdrawn than their classmates (Stokes *et al.*, 1991).

More than 40% of individuals with TS experience recurrent OC symptoms (Leckman *et al.*, 1994, 1997; Khalifa & von Knorring, 2005; Ferrão *et al.*, 2013). Genetic, neurobiological, and treatment response studies suggest that there may be qualitative differences between tic-related forms of OCD and cases of OCD in which there is no personal or family history of tics. Specifically, tic-related OCD has a male preponderance, an earlier age of onset, a poorer level of response to standard anti-obsessional medications, and a greater likelihood of first-degree family members with a tic disorder (Hounie *et al.*, 2006). Symptomatically the most common OC symptoms encountered in TS patients are obsessions concerning a need for symmetry or exactness, repeating rituals, counting compulsions, and ordering/arranging compulsions (Leckman *et al.*, 1997). Also, OC symptoms, when present in children with TS, appear more likely to persist into adulthood than the tics themselves (Bloch *et al.*, 2006a).

The co-occurrence of *depression* and *anxiety* symptoms with TS are commonplace and may reflect the cumulative psychosocial burden of having tics or shared etiological factors or both (Cath & Ludolph, 2013). Antecedent depressive symptoms do predict modest increases in tic severity (Lin *et al.*, 2007). However, this study also documented that future depression severity is more closely associated with antecedent worsening of psychosocial stress and OC symptoms than it is with future measures of tic severity.

Children with a range of neurodevelopmental disorders are at increased risk for tic disorders. Kurlan and colleagues (1994) reported a fourfold increase in the prevalence of tic disorders among children in special educational settings in a single school district in upstate New York. These children did not have an intellectual disability but did have significant specific learning problems, and/or other speech or physical impairments. Children with autism and other pervasive developmental disorders are also at higher risk for developing TS (Baron-Cohen *et al.*, 1999; Cath & Ludolph, 2013). However, in many instances the tics go unrecognized and regarded as stereotypes.

A number of medical and neurological disorders have a higher prevalence in children with TS. These include asthma and allergic disorders, streptococcal infections, as well as restless legs syndrome, and migraine and tension headaches (Lespérance *et al.*, 2004; Chang *et al.*, 2011; Ghosh *et al.*, 2012; Murphy, 2013). The etiological basis for these associations is yet to be elucidated.

Prognosis and quality of life

Prospective cohort studies have fairly consistently shown that most children with TS will improve during adolescence (range: 67–96%) (Bloch, 2013). Current research indicates that estimates of current tic severity have limited value in terms of long-term prognosis. Although lifetime histories of comorbid ADHD and OCD symptoms are associated with poorer

adulthood psychosocial functioning in patients with TS, the presence of these comorbid symptoms in childhood has not been found to be associated with higher levels of severity in adulthood (Bloch *et al.*, 2006b; Gorman *et al.*, 2010). However, initial studies do suggest that poor performance on standardized tests of fine-motor coordination (dominant hand, Purdue Pegboard test) and smaller caudate nucleus volumes (using volumetric MRIs) are associated with more severe tic symptoms in adulthood (Bloch *et al.*, 2005; Bloch *et al.*, 2006b).

Over the past two decades, several studies have documented that many children, adolescents, and adults with TS may have a reduced *Quality of Life* (Elstner *et al.*, 2001; Sukhodolsky *et al.*, 2013). Cavanna and colleagues (2008) developed the Gilles de la Tourette's Syndrome-Quality of Life Scale. The relative contribution of tics versus other co-occurring conditions to impairments in adaptive functioning is an active area of research. In a recent study, 50 children with “pure” TS had a higher quality of life than did individuals with TS, ADHD, and OCD (Eddy *et al.*, 2012). Careful clinical evaluation is required to understand profiles of strengths and weaknesses in adaptive functioning and to disentangle the relative contributions of tics and co-occurring disorders from other problems with peers, academic functioning, or family life. Whenever possible, clinical interviews should be supplemented by collecting standardized ratings of adaptive functioning.

Risk factors

Genetic risk factors

Twin and family studies provide evidence that genetic factors are involved in the vulnerability to TS and related disorders (Pauls & Leckman, 1986; Fernandez & State, 2013). The concordance rate for TS among monozygotic twin pairs is greater than 50% while the concordance of dizygotic twin pairs is about 10% (Price *et al.*, 1985). If cotwins with chronic motor tic disorder are included, these concordance figures increase to 77% for monozygotic and 30% for dizygotic twin pairs. These differences in the concordance of monozygotic and dizygotic twin pairs indicate that genetic factors play an important role in the etiology, but the fact that concordance for monozygotic twins is less than 100% also indicates that nongenetic factors are critical in determining the nature and severity of the clinical syndrome.

Other studies indicate that first-degree family members of probands with TS are at substantially higher risk for having TS, chronic motor tic disorder, and OCD than unrelated individuals (Pauls *et al.*, 1991). The rates are substantially higher than might be expected by chance in the general population, and greatly exceed the rates for these disorders among the relatives of individuals with other psychiatric disorders except OCD.

The pattern of vertical transmission among family members has led several groups of investigators to test specific genetic hypotheses. While not definitive, segregation analyses

could not rule out autosomal transmission (Pauls & Leckman, 1986). However, subsequent efforts to identify susceptibility genes within large multigenerational families or using affected sibling pair or genome-wide association designs have met with limited success (Fernandez & State, 2013). The one exception is the report by Ercan-Sencicek *et al.* (2010) that described a two-generation family with nine affected members with TS. They eventually identified a rare functional mutation in the gene encoding L-histidine decarboxylase, the rate-limiting enzyme in histamine biosynthesis.

In addition, a number of cytogenetic abnormalities have been reported in TS families (State *et al.*, 2003; Cuker *et al.*, 2004). Verkerk and colleagues (2003) reported the disruption of the contactin-associated protein 2 gene on chromosome 7. This gene encodes a membrane protein located at nodes of Ranvier of axons that may be important for the distribution of the K(+) channels, which would affect signal conduction along myelinated neurons. In addition, using a candidate gene approach identified by chromosomal anomalies, Abelson *et al.* (2005) identified and mapped a de novo chromosome 13 inversion in a patient with TS. The gene *SLITRK1* was found to be expressed in multiple neuroanatomical areas implicated in TS neuropathology.

Microarray technologies that can detect submicroscopic structural variation have revealed extensive copy number variation (CNV) throughout the human genome (Conrad *et al.*, 2010) and provided new opportunities for genome-wide studies of such variation in TS and other neurodevelopmental disorders. Initial CNV studies have identified multiple rare variants in TS and hypothesized an overlap of risk with autism and other neurodevelopmental disorders (Sundaram *et al.*, 2010; Fernandez *et al.*, 2012). Further studies are needed to clarify the importance of these variants.

In sum, there are a number of promising leads in the field of genetics. For example, several lines of evidence suggest that histaminergic neurotransmission modulates dopamine release (Ferrada *et al.*, 2008). The technology is now available to explore the role of variations in noncoding RNA as well as the impact of epigenetic modifications of DNA methylation and chromatin remodeling on patterns of gene expression that may be due in part to environmental adversity.

Perinatal risk factors

Twin studies, despite their small size and number, have consistently demonstrated that nongenetic factors play a role in the pathogenesis of TS (Fernandez & State, 2013). Among the risk factors most consistently documented, adverse perinatal problems and infectious and immunological events have been the most consistently implicated.

The most straightforward method of investigating the potential role of perinatal complications in the pathogenesis of TS is to compare the frequencies of these events in children with TS (or tics in general) to a matched group of healthy control children. A number of such case-control studies have been published

(Hoekstra, 2013). In a pioneering study, Pasamanick and Kawi (1956) reviewed the hospital obstetrical records of a cohort of 83 children of normal intelligence diagnosed as “tiqueurs” at Johns Hopkins Medical Center and compared these with the obstetrical records of the very next newborn reported from the same hospital as the child with tics, matched by race, sex, and maternal age group. The percentage of mothers of children with tics with one or more complications was 33.3%, compared with 17.6% for the controls; the percentage of those with two or more complications in the tic group was 7.8% versus only 2.0% in the healthy controls. Subsequently a number of associations have been reported, including advanced paternal age, severe maternal psychosocial stress during pregnancy, severe nausea and/or vomiting during the first trimester, maternal smoking during pregnancy, more and earlier prenatal care visits, delivery complications, and low Apgar score at 5 min after birth (Hoekstra, 2013). Maternal smoking during pregnancy and low birth weight are risk factors for the presence of comorbid ADHD in individuals with a tic disorder. Older paternal age, maternal use of coffee, cigarettes, or alcohol during pregnancy and forceps deliveries are risk factors for the presence of comorbid OCD in individuals with a tic disorder.

A number of fundamental questions remain in this area of research, including whether or not there is a real cause-effect relationship between perinatal adversities and tic disorders (see Chapters 9 and 12). If this can be documented, it will be important to determine what the pathogenic mechanisms are by which perinatal adversities lead to chronic tics over the course of CNS development. Other related questions pertain to the potential presence of critical periods in brain development and the role of genetic risk factors or the possible involvement of epigenetic alterations leading to enduring changes in the levels of gene expression in specific brain regions.

Gender-specific endocrine factors

Males are more frequently affected with TS than females (Shapiro *et al.*, 1988), but male-to-male transmission within families rules out the presence of an X-linked vulnerability gene. This observation has led to the hypothesis that androgenic steroids act at key developmental periods to influence the natural history of TS and related disorders (Peterson *et al.*, 1992). These developmental periods include the prenatal period when the brain is being formed, adrenarche when adrenal androgens first appear at age 5–7 years, and puberty. Androgenic steroids may be responsible for these effects or they may act indirectly through estrogens formed in key brain regions by the aromatization of testosterone (see Chapters 3 and 9).

The importance of gender differences in expression of associated phenotypes is also clear, given the observation that women are more likely than men to develop OC symptoms without concomitant tics (Pauls *et al.*, 1991), and that boys with TS are much more likely than girls to display ADHD and disruptive behaviors.

Surges in testosterone and other androgenic steroids during critical periods in fetal development are involved in the production of long-term functional augmentation of subsequent hormonal challenges (as in adrenarche and during puberty) and in the formation of structural CNS dimorphisms (Goy *et al.*, 1988; Sikich & Todd, 1988). Sexually dimorphic brain regions include portions of the amygdala (and related limbic areas) and the hypothalamus (including the medial preoptic area that mediates the body's response to thermal stress) (Boulant, 1981). These regions contain high levels of androgen and estrogen receptors and influence activity in the basal ganglia both directly and indirectly. Indeed, a proportion of patients with TS appear to be uniquely sensitive to thermal stress and when their core body temperature increases and they begin to sweat, their tics increase (Lombroso *et al.*, 1991). It is also of note that some of the neurochemical and neuropeptidergic systems implicated in TS and related disorders, such as dopamine, serotonin, and the opioids, are involved with these regions and appear to be regulated by sex-specific factors.

Further support for a role for androgens comes from anecdotal reports of tic exacerbation following androgen use (Leckman & Scahill, 1990) and from trials of antiandrogens in patients with severe TS and/or OCD (Peterson *et al.*, 1998b). In the most rigorous study to date, Peterson and colleagues (1998b) found that the therapeutic effects of the antiandrogen, flutamide, were modest in magnitude and these effects were short-lived, possibly because of physiologic compensation for androgen receptor blockade.

Psychosocial stress

Tic disorders have long been identified as “stress-sensitive” conditions. Typically, symptom exacerbations follow in the wake of stressful life events. As noted by Shapiro and colleagues (1988), these events need not be adverse in character. However, clinical experience suggests that in some instances a vicious cycle is initiated in which attempts to suppress the symptoms by punishment and humiliation lead to a further exacerbation of symptoms and further increase in stress in the child's interpersonal environment. Unchecked, this vicious cycle can lead to the most severe manifestations of TS. Prospective longitudinal studies have shown that patients with TS experience more stress than matched healthy controls (Findley *et al.*, 2003) and that antecedent stress may play a role in subsequent tic exacerbation (Lin *et al.*, 2007, 2010). Increases in depressive symptoms have also emerged as a significant predictor of future tic severity.

In addition to the effects of stress, anxiety, and depression, premorbid stress may also act as a sensitizing agent in the pathogenesis of TS among vulnerable individuals (Leckman *et al.*, 1984). It is likely that the immediate family environment, for example, parental discord, and the coping abilities of family members play some role (Leckman *et al.*, 1990), and this may lead to a sensitization of stress-responsive biological systems such as the hypothalamic–pituitary–adrenal axis (Chappell *et al.*, 1994, 1996; Leckman *et al.*, 1995).

Antecedent infections and immune responses

The relationship between antecedent infections and immune responses has been an object of interest for clinical and basic researchers for centuries (Kushner, 1999). For example, Sydenham's chorea is known to be an autoimmune disorder following group A beta-hemolytic streptococcus (GABHS) infections (Dale & Brilot, 2012). Among the clinical manifestations of Sydenham's chorea, OCD as well as motor and vocal tics are not uncommon (Mercadante *et al.*, 2000). In addition to GABHS, *Mycoplasma pneumoniae*, *Borrelia burgdorferi*, as well as viral agents such as varicella zoster, have all been reported as potential causes of “postinfectious tourettism” in anecdotal reports as well as in larger observational clinical series (Murphy, 2013).

It has been proposed that Pediatric Autoimmune Neuropsychiatric Disorder Associated with Streptococcal (PANDAS) infection represents a distinct clinical entity, and includes Sydenham's chorea and some cases of TS and OCD (Swedo *et al.*, 1998) (see also Chapter 61). The most compelling evidence of an etiological link between these disorders and GABHS infection comes from a study that found an increased proportion of GABHS infections (odds ratio = 13.6) within the preceding 12 months in children newly diagnosed with TS compared to well-matched controls (Mell *et al.*, 2005). The PANDAS hypothesis is also indirectly supported by the presence of high levels of antistreptococcal antibodies in some patients with TS (Cardona & Orefici, 2001; Church *et al.*, 2003; Martino *et al.*, 2011). Animal model systems have also been developed that provide proof of concept for PANDAS (Yaddanapudi *et al.*, 2010; Brimberg *et al.*, 2012). Thus far, however, prospective longitudinal studies have provided little support for the idea that GABHS infections induce future tic exacerbations (Kurlan *et al.*, 2008; Leckman *et al.*, 2011). These findings have led in part to a reformulation of the PANDAS concept, with a greater emphasis now being placed on the overnight onset of OCD as the cardinal feature of pediatric acute-onset neuropsychiatric syndrome (PANS) (Swedo *et al.*, 2012). The PANS concept also removes the requirement for an antecedent GABHS infection. Ideally, this will allow investigators to identify similar cohorts of children and to explore a range of possible etiological factors.

There is also a growing literature that suggests possible systemic alterations of circulating levels of proinflammatory cytokines, immunoglobulins, and immune cells in TS (Martino, 2014). For example, there is preliminary evidence of decreased numbers of regulatory T-cells during periods of tic exacerbation (Kawikova *et al.*, 2007). A number of genes related to both cell- and antibody-mediated immune responses have been reported to be overexpressed in peripheral blood (Lit *et al.*, 2007, 2009). Preliminary postmortem studies also support the presence of neuroinflammatory processes in some adults with severe persistent TS (Morer *et al.*, 2010).

Finally, it should be noted that neuroimmunology is an emerging area of scientific discovery. For example, although microglia are the resident macrophages of the brain, and act as the first and main form of active immune defense in CNS, it is

also clear that microglia and the proteins that they produce are not synonymous with inflammation. Indeed, microglia appear to play an important and ongoing role in surveying and shaping neuronal circuit structure and function over the lifespan (Wake *et al.*, 2013). In addition, some “proinflammatory” cytokines, proteins of the innate immune system, and components of the major histocompatibility complex, complement proteins, and various T- and B-cell receptors play essential roles in the establishment and modulation of synaptic connections during development (Yirmiya & Goshen, 2011). These effects occurring over the course of neural development set the stage for a deeper understanding of the neuroanatomy and circuit anomalies seen in TS and other neurodevelopmental disorders.

Pathophysiology

Neural circuits

Investigators interested in procedural learning, habit formation, and internally and externally guided motor control have focused their attention on multisynaptic cortico-striato-thalamo-cortical (CSTC) circuits or loops that link the cerebral cortex with several subcortical regions (Graybiel & Canales, 2001). As a result, the most widely accepted neuroanatomical model of TS proposes a regional imbalance of the direct versus the indirect pathway (Figure 56.2) within one or

more of these CSTCs (Albin & Mink, 2006). In the direct pathway, an excitatory glutamatergic signal projects to the striatum, sending an inhibitory γ -aminobutyric acid (GABA)-ergic signal to the internal part of the globus pallidus. This signal results in a decreased inhibition (disinhibition) of the thalamus and thus an increased excitatory effect on the prefrontal cortex. In the indirect pathway, the striatum projects an inhibitory signal to the external part of the globus pallidus and the subthalamic nucleus, sending an excitatory signal to the internal part of the globus pallidus. The net effect is an increased inhibition of the thalamus and decreased excitation on the prefrontal cortex. It is hypothesized that the direct pathway functions as a self-reinforcing positive feedback loop and contributes to the initiation and continuation of behaviors, whereas the indirect pathway provides a mechanism of negative feedback, which is important for the inhibition of behaviors and in switching between behaviors. Based on postmortem studies, as well as structural and functional neuroimaging studies, it appears that an imbalance between these frontal-striatal circuits might mediate tic symptomatology as well as that of related disorders.

Neuropathology

Although neuropathological studies of postmortem TS brains are few in number, a recent stereological study indicates that there is a marked alteration in the number and density of at least two classes of interneurons (parvalbumin-positive fast-spiking

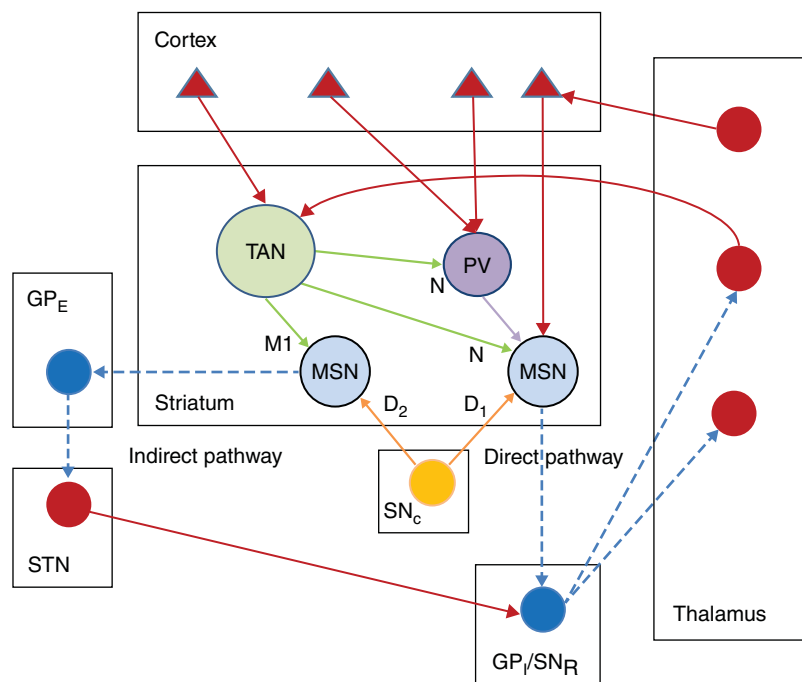

Figure 56.2 Cortico-striato-thalamo-cortical circuitry in Tourette’s syndrome. Red, excitatory glutamatergic neurons; blue, GABAergic inhibitory neurons; green, cholinergic tonically active interneurons (TANs); orange, dopaminergic neurons. Parvalbumin fast-spiking GABAergic interneurons (PVs, parvalbumins) mediate the cortical feed-forward inhibition upon medium spiny neurons (MSNs) of the striatopallidal direct pathway, resulting in inhibition of voluntary movements. Cholinergic TANs enhance the responsiveness of MSNs of the striatonigral indirect pathway, resulting in movement suppression. PVs and TANs are diminished in number in the brains of adults with severe, persistent Tourette’s syndrome (see text). The volume of the striatum, particularly the caudate nuclei, is smaller in both children and adults with Tourette’s syndrome. Receptors include: M1 and nicotinic (N) cholinergic receptors; D₁ and D₂ dopamine receptors. *Source:* Adapted with permission from Vaccarino *et al.* (2013).

GABAergic interneurons and cholinergic tonically active neurons) in the caudate and putamen (Kalanithi *et al.*, 2005; Kataoka *et al.*, 2010). Most recently, Lenington *et al.* (2014) reported on the results of a whole transcriptome analyses of the basal ganglia of 9 adults with TS. They found a down regulation of striatal interneuron transcripts associated with cholinergic and GABAergic interneurons. They also observed a marked increase in immune-related genes, consistent with activation of microglia in the striatum. Further studies are needed to confirm and extend these findings. A key question concerns whether these alterations are causal or simply a consequence of having lifelong TS (Leckman *et al.*, 2006).

Structural brain imaging

Volumetric magnetic resonance imaging (MRI) studies of basal ganglia in individuals with TS are largely consistent with these postmortem results—with the finding of a slight reduction in caudate volume (Hyde *et al.*, 1995; Peterson *et al.*, 2003). For example, in a study of 154 subjects with TS and 130 healthy controls, Peterson *et al.* (2003) found a significant decrease in the volume of the caudate nucleus in both children and adults. Although there was no correlation between symptom severity and caudate volumes in this cross-sectional study, Bloch *et al.* (2005) found an inverse correlation between caudate volumes measured in childhood and tic severity rated in early adulthood.

Cortical thinning in sensorimotor cortices has also been detected in children and adults with TS, with a negative correlation between thickness and orofacial tic severity (Sowell *et al.*, 2008). Several portions of the brain, including the prefrontal cortex, the corpus callosum, amygdala, and hippocampus have been proposed to constitute a network of neural adaptation to the presence of tics, a network in which compensatory changes help to suppress or modulate the severity of tic symptoms (Plessen *et al.*, 2009). Recently, Bansal *et al.* (2012) employed a semisupervised learning algorithm to identify spatial patterns of variation in the morphology of the cerebral cortex and other brain regions that were specifically associated with TS. Regional volumes and surface features morphology of the right hippocampus and the right globus pallidus provided the best sensitivity and specificity.

Functional brain imaging

There are a growing number of studies using functional magnetic resonance imaging (fMRI) to study individuals with TS. In one of the first, Peterson *et al.* (1998a) compared brain activity during blocks of time during which tics were voluntarily suppressed or not suppressed. During tic suppression, prefrontal cortical, thalamic, and basal ganglia areas were activated. These activations were inversely correlated with tic severity (i.e., lower activation was associated with higher tic severity). This suggests that a greater ability of basal ganglia to suppress cortical activity might be linked with decreased tic severity, and is in agreement with single photon emission-computed tomography (SPECT) and positron emission tomography (PET) studies that

suggest involvement of the basal ganglia in TS (Braun *et al.*, 1995). More recently, Kumar *et al.* (2014) has documented activated microglia-mediated neuroinflammation in the caudate nuclei bilaterally using PET adolescents with TS. This finding is consistent with the whole transcriptome findings reported by Lenington *et al.* (2014). Bohlhalter *et al.* (2006) studied the neural correlates of tics and associated urges using an event-related fMRI protocol. On the basis of synchronized video/audio recordings, fMRI activities were analyzed 2 s before and at tic onset. A brain network of paralimbic areas including the anterior cingulate and insular cortex, supplementary motor area, and parietal operculum was found to be activated before tic onset. In contrast, at the beginning of tic action, significant fMRI activities were found in sensorimotor areas including superior parietal lobule bilaterally and cerebellum. Similar results were reported by Hampson (2009) who found that the spatiotemporal pattern of coactivation was similar for both the healthy controls and the TS subjects. However, the timing and magnitude of the activation in the supplementary motor area differed in the TS, perhaps reflecting the importance of this region in relation to the premonitory sensory urges.

Resting-state functional connectivity has also been studied in adolescents and adults with TS (Church *et al.*, 2009). Results demonstrated widespread functional immaturity in both the frontoparietal and the cingulo-opercular networks. In addition, a number of anomalous connections, not seen in age-match peers, were also identified, primarily in the frontoparietal network. These findings are consistent with studies using diffusion tensor imaging that again reveal altered interhemispheric connectivity in individuals with TS (Neuner *et al.*, 2010).

Neurophysiology

Noninvasive *in vivo* neurophysiological research in TS has led to several areas of significant progress. The first concerns the use of a startle paradigm to measure inhibitory deficits by monitoring the reduction in startle reflex magnitude. Swerdlow *et al.* (2001) have confirmed and extended earlier findings indicating that patients with TS have deficits in sensory gating across a number of sensory modalities. Prepulse inhibition abnormalities have been observed across a variety of neuropsychiatric populations, including schizophrenia, OCD, Huntington's disease, nocturnal enuresis, ADHD, Asperger's syndrome, and TS, suggesting that some final common pathways mediate abnormal prepulse inhibition in all of these conditions. With respect to TS, these deficits are consistent with the idea that there is diminished ability to appropriately manage or "gate" sensory inputs to motor programs, which are released as tics (Swerdlow & Sutherland, 2006; Zebardast *et al.*, 2013). A second advance has been the investigation of motor system excitability by means of single and paired pulse transcranial magnetic stimulation. Studies of groups of patients with TS have indicated that the cortical silent period (a period of decreased excitability following stimulation) is shortened. This intracortical excitability is frequently seen in children with ADHD comorbid with a tic disorder (Ziemann

et al., 1997; Moll *et al.*, 1999). This heightened level of cortical excitability may be related to a reduction in the number of GABAergic interneurons in the cortex. Third, Serrien *et al.* (2005) identified similar sensorimotor-frontal connections involved in the acute suppression of involuntary tics as evidenced by increased EEG coherence in the α frequency band (8–12 Hz) during suppression of voluntary movements in individuals with TS and healthy subjects during a Go-NoGo task. This finding, taken with the functional findings from Peterson *et al.* (1998a), suggests that the frontal lobes may play a key role in tic suppression, and coherence in the α band may be part of this process. The combination of imaging techniques with real-time neurophysiological techniques, such as electroencephalography or magnetoencephalography, may help to determine whether any abnormalities seen in brain imaging contribute to the production of tics or whether they constitute a compensatory response (Llinas *et al.*, 2005; Leckman *et al.*, 2006).

Neurotransmitter systems

Extensive immunohistochemical studies of the basal ganglia have demonstrated the presence of a wide spectrum of classic neurotransmitters, neuromodulators, and neuropeptides. The most compelling data have implicated central dopaminergic systems in the pathobiology of TS (Albin & Mink, 2006). Of the various dopaminergic hypotheses proposed, an alteration of the tonic-phasic neurotransmitter release system appears most viable (Singer, 2013). However, it remains highly likely that TS patients exhibit dysfunction in several neurotransmitter systems, including serotonergic, glutamatergic, GABAergic, cholinergic, and possibly histaminergic pathways.

Treatment

Tic disorders are frequently chronic, if not lifelong, conditions. Continuity of care is desirable and should be considered before embarking on a course of treatment. Usual clinical practice focuses initially on educational and supportive interventions. Pharmacological treatments are typically held in reserve. Given the waxing and waning course of the disorders, it is likely that whatever is done (or not done) will lead in the short term to some improvement in tic severity. The decision to employ psychoactive medications is usually made after the educational and supportive interventions have been in place for a period of months and it is clear that the tic symptoms are persistently severe and are themselves a source of impairment in terms of self-esteem, relationships with the family or peers, or school performance.

Educational and supportive interventions

Educational activities are among the most important interventions available to the clinician (Lebowitz and Scahill, 2013). They should be undertaken first, not only with children with

TS but also with those with milder presentations. Although the efficacy of these educational and supportive interventions has not been rigorously assessed, they appear to have positive effects by reshaping familial expectations and relationships (Cohen *et al.*, 1988). This is particularly true when the family and others have misconstrued the tic symptoms as being intentionally provocative. Families also find descriptions of the natural history comforting in that the disorders tend not to be relentlessly progressive and usually improve during adulthood. This information often contradicts the impressions gained from the available lay literature on TS that typically focuses on the most extreme cases. Armed with this knowledge, patients and family members and others can begin to understand why waiting before beginning medical treatment makes sense. If a child is in the midst of a bad period of tics, it is likely that whether or not a new medication is prescribed, the tics will improve in the near future. This insight will also help children and their families realize why at times in the past their medications have suddenly stopped working. These dialogs can be relieving and can interrupt a vicious cycle of recrimination that leads to further tic exacerbation and it can help parents shift the focus from blame to problem solving.

By educating the educators, clinicians can make significant progress toward securing for the child a positive and supportive environment in the classroom (Pruitt & Packer, 2013). If possible, teachers need to respond to outbursts of tics with grace and understanding. Repeatedly scolding a child for his tics can be counterproductive. The child may develop a negative attitude to authority figures and may be reluctant to attend school, and classmates may feel freer to tease the child. If tics interfere with a student's ability to receive information in the classroom, it is imperative to find alternative ways to present the material. By helping the student find a way to function even during periods of severe tics, teachers model problem-solving skills that will foster future self-esteem. It is also important for teachers to know that in unstructured settings such as the cafeteria, gym, playground, and school bus, peers who tease or taunt tend to take advantage of the lack of adult supervision. The assignment of a paraprofessional aide to accompany the student can be remarkably beneficial—particularly in situations where there is a history of teasing. Other useful strategies that teachers may consider include providing short breaks out of the classroom to let the tics out in private, allowing students with severe tics to take tests in private so that a child does not have the pressure to suppress tics during the test period, and being flexible with regard to scheduling so that the child is not expected to make an oral presentation at a point when the tics are severe (Bronheim, 1991). A compendium of educational accommodations is available at: <http://www.tourettesyndrome.net/>.

Educated peers are equally important. Many clinicians actively encourage children, families, and teachers to help educate peers and classmates about TS. It is remarkable what can be tolerated in the classroom and on the playground when teachers and peers simply know what the problem is and learn to disregard it.

Finally, it is important for clinicians to determine the family's awareness of and potential interest in advocacy organizations such as the Tourette Action (www.tourettes-action.org.uk/); Tourette's Syndrome Association (www.tsa-usa.org/); the International Obsessive Compulsive Foundation (<http://www.ocfoundation.org/>); and the Children and Adults with Attention Deficit Disorder (<http://www.chadd.org/>). These organizations have made a positive contribution to the lives of many patients and their families by providing support and information. They can also be a valuable outlet for families—to advance research and raise the general level of awareness among health care professionals, educators, and the public at large.

Behavioral, cognitive, and other psychotherapeutic treatments

The presence of premonitory urges and the characteristic suppressibility of tic symptoms may have broad implications for behavioral interventions and treatment. Prior to seeking professional consultation, many families will have experimented with a variety of *ad hoc* behavioral approaches on their own. It is useful to elicit information concerning these efforts and their sequelae.

A variety of cognitive and behavioral approaches have been used with TS (Capriotti & Woods, 2013). Although success with various techniques such as assertiveness training, biofeedback, massed practice, time-out, hypnosis, and differential reinforcement has been reported, most of these studies have involved small numbers of poorly characterized participants with no replication. To date, only Habit Reversal Training, also known as Comprehensive Behavioral Intervention for Tics (C-BIT), has been shown to be efficacious in two large multisite clinical trials involving both children and adults with TS (Piacentini *et al.*, 2010; Wilhelm *et al.*, 2012). Medium effect sizes were found in both the pediatric ($ES = 0.68$) and the adult ($ES = 0.57$) trials. C-BIT is now considered to be the first-line treatment for children above the age of 9 years.

C-BIT includes a number of techniques: awareness training, self-monitoring, contingency management, inconvenience review, relaxation, and competing responses. For example, awareness training includes: (i) response description, that is, the patient is trained to describe tic occurrences in detail and to re-enact tic movements while looking in a mirror; (ii) response detection, where the therapist helps the patient's ability to detect tics; (iii) an early warning procedure, in which the patient is taught to become aware of the earliest signs of tic occurrence (such as the premonitory urge); and (iv) situation awareness training in which situations that make tics more likely are identified. When the patient is able to detect the tic and related urges, he or she is instructed to invoke a Competing Response at each occurrence of the tic or the urge and to hold it until the urge passes. Historically, a Competing Response involved a voluntary act that is physically incompatible with production of a particular motor or vocal tic, for example, humming instead of making a vocal tic or slightly tilting one's head to the left when the tic involves a sudden tilt to the right. More recent applications have

been less strict, deemphasizing tensing of opposite muscles and occasionally selecting unrelated alternative behaviors.

Researchers are also now exploring the possibility of adding acceptance-based cognitive components to Habit Reversal Training to enhance treatment outcomes. In this intervention, a standard Habit Reversal Training was integrated with a TS-specific version of Acceptance and Commitment Therapy (ACT; Franklin *et al.*, 2011). In general, ACT aims to improve patients' functioning by offering exercises to distance patients from distressing cognitions/urges and other distressing emotions. As applied to TS, ACT focuses on teaching skills to behave flexibly in the presence of (i) uncomfortable premonitory urges, (ii) emotional distress associated with the tics (e.g., embarrassment about occurrence of tics in public or when meeting someone new or recalling past events), and/or (iii) cognitive symptoms associated with comorbid psychiatric conditions such as OCD and ADHD. Future trials are needed to determine whether the presence of ADHD has a negative impact on the treatment outcomes following CBIT.

Exposure and Response Prevention is another promising behavioral treatment for chronic tics (Piacentini & Chang, 2006). As applied to tics, Exposure and Response Prevention focuses on exposure to the premonitory urges. Exposure to the urge occurs by having the patient suppress the tics for long periods of time while the therapist "coaches" him or her through the process (Verdellen *et al.*, 2008). Unlike C-BIT, Exposure and Response Prevention does not teach specific strategies for inhibiting tics. Larger randomized clinical trials are needed to establish the relative efficacy of Exposure and Response Prevention to C-BIT.

Some individuals with TS, or at least many clinically referred patients, report disruptive behavioral symptoms characterized by sudden and unpredictable anger, irritability, temper outbursts, self-injurious behavior, and aggression. In many cases, these symptoms are intertwined with each other and with OCD and ADHD symptoms. Children with this type of disruptive behavior are a difficult-to-treat population, as they are noncompliant almost by definition. Anecdotally, the use of Functional Behavioral Analysis has been of value in some cases.

Pharmacological treatments

The decision whether or not to use medication is based on the level of symptoms and the clinical presentation of the individual case. Given the waxing and waning of tic symptoms, it is best to withhold psychotropic medications until the tics, even at their best, are a significant source of impairment. Many cases of TS can be successfully managed without medication. When patients present with coexisting ADHD, OCD, depression, or bipolar illness, it is often better to treat these comorbid conditions first, as successful treatment of these disorders will often diminish tic severity.

Pharmacotherapy of tics

A wide variety of therapeutic agents are now available to treat tics (Singer, 2010; Roessner & Rothenberger, 2013). The goal should be to use as little medication as possible to render the tics more “tolerable.” Efforts to stop the tics completely risk overmedication. Each medication should be selected on the basis of expected efficacy and potential side effects.

Clonidine and guanfacine are potent α 2-receptor agonists that are thought to function by stimulating postsynaptic α -2A receptors on dendritic spines of the prefrontal cortical pyramidal cells and by increasing the functional connectivity of the prefrontal cortical networks (Arnsten, 2010). Initial randomized trials of clonidine had mixed results. A subsequent trial involving 136 subjects with chronic tics or TS confirmed clonidine’s efficacy in the treatment of tics with comorbid ADHD (Tourette’s Syndrome Study Group, 2002). A recent meta-analysis of six randomized, placebo-controlled trials demonstrated that α -2 agonists had a medium effect size ($ES = 0.68$) in reducing tic symptoms in trials in which participants also had ADHD. However, in the absence of ADHD, the efficacy of these agents was small ($ES = 0.15$) and nonsignificant (Weisman *et al.*, 2012). Although this finding calls into question existing treatment guidelines for TS that recommend α -2 agonists as first-line pharmacological treatment of tics (Singer, 2010), the available studies for review were few in number and sample sizes were small. Consequently, firm conclusions cannot be drawn due to the less than adequate state of current evidence. Guanfacine is generally preferred to clonidine because it is less sedating and not associated with rebound hypertension following withdrawal. Guanfacine is generally started at a dose of 0.5 mg at night and then gradually increased by 0.5 mg roughly weekly to TID dosing with a maximum dose being 4 mg daily (Singer, 2010; Roessner & Rothenberger, 2013). Unfortunately, guanfacine is not widely available outside the United States.

Classic dopamine D_2 receptor antagonists remain the most predictably effective tic-suppressing agents in the short term. Documentation of haloperidol’s effectiveness in the early 1960s was a landmark in the history of TS as it called into question the prevailing view that tics were psychogenic in origin. The most widely used typical D_2 receptor antagonists are haloperidol, pimozide, fluphenazine, and tiapride. Tiapride is not presently available in the United States but is widely used in the United Kingdom and continental Europe. Favorable data from double-blind clinical trials are available for three of these agents (haloperidol, pimozide, and tiapride) (Eggers *et al.*, 1988; Shapiro *et al.*, 1989; Sallee *et al.*, 1997; Tourette’s Syndrome Study Group, 1999). Potential side effects associated with typical neuroleptics include acute dystonia, sedation, depression, school and social phobias, weight gain, and tardive dyskinesia. Consequently, long-term experience has not been particularly favorable, so the “reflexive” use of these agents should be avoided.

To avoid the extrapyramidal side effects associated with typical neuroleptics, atypical neuroleptics, such as risperidone,

olanzapine, ziprasidone, and aripiprazole have been used to treat tic symptoms. These agents have potent 5-HT₂ blocking effects as well as more modest blocking effects on dopamine D_2 . Four randomized controlled trials have shown that risperidone was superior to placebo (Bruggeman *et al.*, 2001; Dion *et al.*, 2002; Gaffney *et al.*, 2002; Scahill *et al.*, 2003). Doses ranging from 1.5 to 3.5 mg/day were effective and neurological side effects were rare. However, a number of adverse effects are commonly associated with the use of these agents (weight gain, lipid metabolism abnormalities, sedation, and sleep disturbance).

Open label pilot studies are available for medications such as tetrabenazine and benzodiazepines. Tetrabenazine is a nonantipsychotic dopamine antagonist, approved as an investigational drug; it may be useful but more study is needed (Singer, 2010; Roessner & Rothenberger, 2013). The benzodiazepines, such as clonazepam, are used as anxiolytics and occasionally used as an adjunctive treatment for tics, though they have not been well studied (Scahill *et al.*, 2006; Singer, 2010). Common side effects with benzodiazepine use include sedation, ataxia, short-term memory problems, disinhibition, depression, and addiction. Given these drawbacks, clonazepam is not used widely to treat TS. The use of botulinum toxin injections to temporarily weaken muscles associated with severe motor or vocal tics also appears effective (Jankovic, 1994; Kwak *et al.*, 2000), and in some cases the recurrent use of botulinum can significantly reduce the premonitory urges associated with both motor and vocal tics in the regions injected. There is also some evidence to support the use of Δ -9-tetrahydrocannabinol (Δ -9-THC) in the treatment of TS (Curtis *et al.*, 2009).

Pharmacotherapy of coexisting ADHD

The stimulants methylphenidate, D-amphetamine, and mixtures of D- and L-amphetamine are first-line agents for the medical management of ADHD (Brown *et al.*, 2005). However, the use of stimulants in ADHD associated with a tic disorder remains controversial. Many patients with both ADHD and a preexisting tic disorder will do well on stimulants. For example, in one large-scale multicenter, randomized, double-blind clinical trial with 136 children with ADHD and a chronic tic disorder, significant improvements in ADHD symptoms occurred for subjects assigned to clonidine alone and those assigned to methylphenidate alone; however, the greatest benefit was seen in those children receiving both medications (Tourette’s Syndrome Study Group, 2002). Compared with placebo, the greatest benefit occurred with combination. Clonidine appeared to be most helpful for impulsivity and hyperactivity, while methylphenidate appeared to be most helpful for inattention. The proportion of individuals reporting a worsening of tics was no higher in those treated with methylphenidate (20%) than those being administered clonidine alone (26%) or placebo (22%). Sedation was common with clonidine treatment (28% reported moderate or severe sedation), but otherwise the drugs were tolerated well, with no evidence of cardiac toxicity. This trial did not support prior recommendations to avoid methylphenidate in

these children because of concerns of worsening tics; however, data from clinical case reports and controlled studies indicate that some children with ADHD will exhibit tics *de novo* when exposed to a stimulant. In particular, supratherapeutic doses of dextroamphetamine should be avoided. In sum, methylphenidate offers the greatest and most immediate improvement of ADHD symptoms and typically does not worsen tic symptoms (Bloch *et al.*, 2009). As noted above, α -2 agonists can also improve ADHD symptoms although patience is required as the beneficial effects are not immediate (Weisman *et al.*, 2012). Atomoxetine, selective norepinephrine reuptake inhibitor, has also been found to reduce ADHD symptoms in children with comorbid tics (Bloch *et al.*, 2009).

Pharmacotherapy of coexisting OCD

The presence of a comorbid tic disorder may predict a poorer outcome in the acute treatment of pediatric-onset OCD. In contrast to cognitive behavioral therapy with Exposure and Response Prevention outcomes, which are not differentially impacted, co-occurring tic disorders appear to impact adversely the outcome of medication management of pediatric OCD (McDougle *et al.*, 1993; March *et al.*, 2007). Consequently, children and adolescents with OCD and a comorbid tic disorder should begin treatment with Exposure and Response Prevention alone or the combination of Exposure and Response Prevention plus a serotonin reuptake inhibitor (SSRI). In adult subjects, controlled clinical trials have also shown that addition of small doses of classical (haloperidol) or atypical neuroleptics (risperidone) can increase the response to SSRIs (Bloch *et al.*, 2006b). The dosage level of the SSRI may also be an important consideration, particularly for older adolescents. In adults with OCD, higher doses are more efficacious than low or medium doses (Bloch *et al.*, 2010). However, the relevance of this observation to younger children and individuals with comorbid tics is unknown.

Pharmacotherapy of cooccurring aggressive behavior (rage attacks)

The management of co-occurring aggressive symptoms and explosive outbursts has not been fully addressed in randomized clinical trials. Preliminary data support the use of aripiprazole in such cases (Budman *et al.*, 2008).

Future directions

Along with a deepening appreciation of the clinical phenomenology and natural history, recent progress in genetics, neuroanatomy, systems neuroscience, and functional *in vivo* neuroimaging has set the stage for major advances in our understanding of TS and related neurodevelopmental disorders (Leckman, 2012). Many mysteries remain, including why there is such a high rate of cooccurring neurodevelopmental disorders in individuals with TS, particularly those with complex motor and vocal tics, relative to individuals with just chronic motor tics. Although TS is etiologically heterogeneous, recent

genetic studies have provided important leads including the suggestion that histaminergic neurotransmission may be a key factor for some families and pharmacological modulation of this system might be beneficial more broadly (Bloch *et al.*, 2011; Fernandez *et al.*, 2012).

The natural history of TS also remains a puzzle (Bloch and Leckman, 2009). What is the neurobiological basis of the usual tic improvement during the second decade of life? Longitudinal studies of the trajectories of brain growth are currently under way to discover how the structure of the TS brain may change over time. These studies have the potential to determine how the regional connectivity may change depending on the course and outcome of the disorder. They may also help explain aspects of the sensorimotor gating abnormalities seen in some individuals with TS (Zebardast *et al.*, 2013).

In addition, a deeper understanding of the role of the immune system in TS and related disorders is urgently needed (Kumar *et al.*, 2014; Lenington *et al.*, 2014; Martino *et al.*, 2014). Key controversies in this area include whether a subset of cases with sudden onset (overnight) of OCD and tics are caused by postinfectious autoimmune processes that parallel what is seen in other movement disorders such as Sydenham's chorea.

The development of C-BIT has been a major advance for the field. Now the challenge is to understand the neural mechanisms underlying this treatment and how best to train a sufficient number of practitioners to ensure access to this intervention. In our estimation, efforts to increase acceptance and reduce stigma are important avenues for the future. Despite these therapeutic advances, we are still in need of ideal antit tic medications that work quickly, effectively, and with few side effects. For interventions currently in use, it will be important to determine the relative long-term benefits of behavioral interventions when combined with drugs.

Acknowledgments

We are indebted to the Yale Tourette's Syndrome; Obsessive-Compulsive Disorder; and Trichotillomania Research Group. Portions of the research described in this review were supported by grants from the National Institutes of Health: MH18268, MH49351, MH30929, HD03008, NS16648, and RR00125, as well as by the Tourette's Syndrome Association.

Schizophrenia and psychosis

Chris Hollis and Lena Palaniyappan

Division of Psychiatry and Applied Psychology, Institute of Mental Health, University of Nottingham, UK

Introduction

Schizophrenia is a particularly devastating psychiatric disorder. Although extremely rare before the age of 10, the incidence of schizophrenia rises steadily through adolescence to reach its peak in early adult life. Early-onset schizophrenia (EOS) arising in childhood and adolescence is now accepted to be clinically and biologically continuous with the adult-onset disorder. The most striking differences associated with early-onset appear to be the greater clinical severity, more frequent and more pronounced early neurodevelopment abnormalities, and poorer treatment response.

The current concept of EOS evolved from a different perspective held during much of the 20th century. Until the early 1970s the term childhood schizophrenia was applied to children who would now be diagnosed with autism. Until the 1990s, there was doubt about the validity of diagnosing schizophrenia in children and younger adolescents. However, in DSM-III and ICD-9 the separate category of childhood schizophrenia was removed, and the same diagnostic criteria for schizophrenia were applied across the age range. Good evidence for the validity of the diagnosis in childhood and adolescence comes from follow-up studies of young people diagnosed with schizophrenia that show a high level of diagnostic stability into adult life and poorer outcomes compared to nonschizophrenic psychoses (Hollis, 2000a). Furthermore, studies of brain structure and function in people diagnosed with schizophrenia have shown very similar types of abnormalities, regardless of the age of onset (Hollis & Rapoport, 2011).

Clinical features

Schizophrenia is characterized by psychotic symptoms. These include:

1 Hallucinations: These are sensory perceptions in the absence of external stimuli. Auditory hallucinations are by far the most

common type of hallucination in schizophrenia. Typically their content is threatening, derogatory, or commanding. Auditory hallucinations are classified according to their form: voices addressing the patient directly (second person); voices discussing or commenting on the patient's actions in the third person (third person or running commentary); and voices speaking the patient's thoughts aloud (thought echo).

2 Delusions: These are false beliefs, incompatible with the patient's social, religious, or educational background, arising from an incorrect inference about external reality and not amenable to reason. Paranoid delusions (belief one is persecuted), delusions of reference (belief that events or people's behavior refer to oneself), or delusions of control (belief that one's own thoughts, emotions, or movements are controlled by external forces), are particularly common in schizophrenia.

3 Passivity phenomena: These include the experience of one's own thoughts becoming automatically available to others (thought broadcast); alien thoughts being inserted into one's mind (thought insertion); and the experience of one's thoughts being removed from one's mind (thought withdrawal).

4 Disordered thought and speech: This may present as incoherent speech (loosening of associations), neologisms, or a paucity of content and ideas (poverty of speech).

5 Reduced or inappropriate emotional reactivity and lack of volition: People with schizophrenia may demonstrate reduced emotional expression (flattened affect) or incongruous emotional reactions, lack of drive and initiative, and social withdrawal.

6 Motor abnormalities: These phenomena may include posturing, mannerisms, stereotypies, and catatonic immobility or excitement.

Symptoms in schizophrenia and psychosis can be seen as either representing an excess or distortion of normal function (positive symptoms) or a reduction or loss of normal function (negative symptoms). Positive symptoms include

hallucinations, delusions, passivity phenomena, thought disorder, disorganized behavior, and inappropriate affect. Negative symptoms include poverty of thought and speech, blunted affect, impaired volition, and social withdrawal. Liddle (1987) showed that symptoms in chronic schizophrenia cluster into three syndromes: psychomotor poverty (negative symptoms); reality distortion (hallucinations and delusions); and disorganization (bizarre behavior, inappropriate affect, and disorganized thought).

A wide variety of anomalous perceptual experiences may occur at the onset of psychosis, leading to a sense of fear or puzzlement which may constitute a delusional mood and herald a full psychotic episode. These anomalous experiences may include the sense that familiar places and people and their reactions have changed in some subtle way, creating a breakdown between perception and memory (e.g., for familiar places and people) and associated affective responses. For example, a young person at the onset of illness may study his/her reflection in the mirror for hours because it looks strangely unfamiliar, or misattribute threatening intent to an innocuous comment, or experience family members or friends as being unfamiliar, leading to a secondary delusional belief that they have been replaced by doubles or aliens. In summary, some clinical phenomena in schizophrenia can be understood in terms of a loss of normal contextualization and coordination of cognitive and emotional processing. The disconnection between perception, memory, and affective response parallels neurobiological descriptions (see section “Neurobiology”).

The clinical phases of schizophrenia

Premorbid social and developmental impairments

EOS is associated with poor premorbid functioning and early developmental delays (Alaghband-Rad *et al.*, 1995; Hollis, 1995, 2003). Similar developmental and social impairments in childhood have been reported in adult-onset schizophrenia, but premorbid impairments appear to be more common and severe in the early-onset form of disorder. In the Maudsley Study (Hollis, 2003), just over 20% of cases of adolescent schizophrenia had significant early delays in either language or motor development. In contrast, language and motor developmental delays occur in about 10% of individuals who develop schizophrenia in adult life (Jones *et al.*, 1994). Impaired sociability occurs in about a third of EOS cases (Hollis, 2003). Premorbid IQ in EOS averages mid to low 80s, some 10–15 points lower than in the adult form of the disorder (Alaghband-Rad *et al.*, 1995; Hollis, 2000b). Around one-third of EOS cases have an IQ below 70, with the whole distribution of IQ shifted down compared to both adolescent affective psychoses and adult schizophrenia (Hollis, 2000b).

Cannon *et al.* (2002) reported a specific association between adult schizophreniform disorder and childhood neurodevelopmental impairments. During childhood, the adult

schizophreniform group when compared to controls had poorer motor skills (0.3 SD), increased neurological signs (OR=4.6), lower IQ scores (0.4 SD), and poorer receptive language skills (0.2–0.6 SD), findings consistent with genetic/neurodevelopmental perspectives. The premorbid phenotype does not just represent nonspecific psychiatric disturbance. Looking backward from schizophrenia to early impairment, subtle problems of language, cognition, attention, and social relationships are typical, while conduct problems are rare. However, looking forward from childhood impairments to later schizophrenia, prediction is much weaker. In addition, premorbid social and behavioral difficulties are not unique to schizophrenia and do occur in other psychoses and overlap with features of neurodevelopmental disorders (e.g., autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD)).

Premorbid psychopathology

Many diagnoses, including ADHD, conduct disorder, anxiety, depression, and ASD, may precede EOS (Schaeffer & Ross, 2002) and adult schizophrenia (Kim-Cohen *et al.*, 2003). However, specificity is not sufficiently strong to aid early identification. More promising research has demonstrated a strong link between self-reported psychotic symptoms in childhood and later schizophrenia. In the Dunedin cohort (Poulton *et al.*, 2000), self-reported psychotic symptoms at age 11 increased the risk of schizophreniform disorder at age 26 but not other psychiatric diagnoses (OR=16.4). Of those with “strong” psychotic symptoms at age 11, 70% developed schizophrenic symptoms by age 26, and 25%, schizophreniform disorder. While none of these met criteria for a diagnosis of schizophrenia during adolescence, it appears that isolated or attenuated psychotic symptoms (Poulton *et al.*, 2000) in combination with developmental impairment (Cannon *et al.*, 2002) constitute an important high-risk premorbid phenotype.

Prodromal symptoms and onset of psychosis

People who develop schizophrenia typically enter a prodromal phase with a gradual but marked decline in social and academic functioning. An insidious deterioration prior to onset of psychosis is typical of the presentation of schizophrenia in children and adolescents (Werry *et al.*, 1994), and is more common in schizophrenia than in affective psychoses (Hollis, 1999). The prodrome is characterized by nonspecific behavioral changes including social withdrawal, declining school performance, uncharacteristic and odd behavior and ideas, eccentric interests, change in affect, and unusual and bizarre perceptual experiences.

At risk mental states

In recent years there has been a growing emphasis on early detection and intervention. This focus has stimulated an interest in prospectively identifying, and potentially intervening in,

so called “at risk mental states” (ARMS) which may precede the onset of the disorder. Unlike the “prodrome” which is a retrospective concept, ARMS describe the clinical characteristics of those thought to be at greatest risk of transition to psychosis or schizophrenia.

ARMS, sometimes also known as “ultra high risk” (UHR) states, are characterized by help-seeking behavior and the presence of attenuated positive symptoms of schizophrenia, brief-limited intermittent psychotic symptoms (BLIPS), or a combination of familial risk indicators with recent functional deterioration. The risk for schizophrenia emerging over a 12-month period is increased in these individuals with between 1 in 5 to 1 in 10 expected to develop a schizophrenia spectrum disorder (Ruhrmann *et al.*, 2010; Fusar-Poli *et al.*, 2012). However, prediction of schizophrenia based on ARMS is modest given that the majority of those identified do not become psychotic. Furthermore, transition rates are lower in young people than adults (Fusar-Poli *et al.*, 2012). Most young people identified with ARMS have a mixture of other mental health problems (e.g., depression, anxiety, substance misuse disorder, and emerging personality disorder) requiring a range of targeted interventions. ARMS may be best viewed as a diagnostically neutral but evolving clinical phase associated with a variety of outcomes rather than a diagnostic category specifically related to schizophrenia. Finally, the potential use of a clinical label that conveys a future risk of psychosis or schizophrenia raises ethical issues and may itself be perceived as stigmatizing. Given the low rate of transition to psychosis, any interventions used must benefit (and not harm) the majority of young people (false-positives) who do not develop psychosis.

Diagnosis of schizophrenia in childhood and adolescence

The two dominant diagnostic systems and International Classification of Diseases (DSM and ICD) have slightly different definitions for schizophrenia, though both require the clear evidence of psychosis (in the absence of predominant affective symptoms) with minimum duration criteria. The reader should refer to the original manuals (DSM-5 and ICD-10) when making diagnoses in clinical or research practice.

Although the same diagnostic criteria apply across the age range, there are developmental variations in phenomenology, with early-onset cases of schizophrenia characterized by a more insidious onset, negative symptoms, hallucinations in different modalities, and fewer systematized or persecutory delusions (Werry *et al.*, 1994). EOS is characterized by greater disorganization (incoherence of thought and disordered sense of self) and more negative symptoms, while in later-onset cases there is a higher frequency of systematized and paranoid delusions (Hafner & Nowotny, 1995).

Course and outcome

Course and prognosis

EOS typically runs a chronic course. Hollis (1999) found that only 12% of patients with schizophrenia were in full remission at discharge from first episode compared to 50% of cases with affective psychoses. The short-term outcome for schizophrenia presenting in early life is worse than for first-episode adult patients (Robinson *et al.*, 1999). If full recovery does occur, then it is most likely within the first 3 months of onset of psychosis. In the Maudsley study, adolescent first-onset patients who were still psychotic after 6 months had only a 15% chance of achieving full remission at follow-up (mean length of follow-up 11.5 years) while over half of all cases that made a full recovery had active psychotic symptoms for less than 3 months (Hollis, 1999).

A number of long-term follow-up studies of EOS describe a typically chronic, unremitting long-term course with severely impaired functioning in adult life (Werry *et al.*, 1991; Hollis, 2000a; Fleischhaker *et al.*, 2005). However, a recent follow-up study from the “EPPIC, Early Psychosis Prevention and Intervention Centre” early intervention psychosis programme in Australia (Amminger *et al.*, 2011) challenges the finding of worse outcome in EOS and reports fewer positive symptoms and better social outcomes for schizophrenia-spectrum disorder with onset at <18 years. A possible explanation is that a lower threshold for recognition and diagnosis of psychosis in EPPIC may have led to inclusion of a larger proportion of good outcome cases than other clinical samples. Several common themes emerge from these studies. First, the generally poor outcome of EOS conceals considerable heterogeneity. About one-fifth of patients have a good outcome with only mild impairment, while at the other extreme about a third of patients are severely impaired requiring intensive social and psychiatric support. Second, after the first few years of illness there is little evidence of further progressive decline. Third, EOS, typically, has a worse outcome than either early-onset affective psychoses or adult-onset schizophrenia. Fourth, social functioning, in particular the ability to form friendships and love relationships, appears to be very impaired in EOS. Taken together, these findings confirm schizophrenia presenting in childhood and adolescence lies at the extreme end of a continuum of phenotypic severity.

The predictors of poor outcome in adolescent-onset psychoses include premorbid social and cognitive impairments (Hollis, 1999; Fleischhaker *et al.*, 2005), a prolonged first psychotic episode (Schmidt *et al.*, 1995), extended duration of untreated psychosis, and the presence of negative symptoms (Hollis, 1999). Premorbid functioning and negative symptoms at onset provide better prediction of long-term outcome than categorical diagnosis (Hollis, 1999; Fleischhaker *et al.*, 2005).

Mortality

The risk of premature death is increased in EOS. In the Maudsley follow-up study (Hollis, 1999), there were nine deaths out of the

106 cases (8.5%), corresponding to a 12-fold increase in the risk of death compared to an age and sex-matched general UK population over the same period. Of the nine deaths in the cohort, three suffered violent deaths, two died from self-poisoning, and three had unexpected deaths due to previously undetected physical causes (cardiomyopathy and status epilepticus) and were possibly associated with high-dose antipsychotic medication.

Epidemiology

Incidence and prevalence

Self-reported psychotic symptoms have a high prevalence in children and adolescents, with a meta-analysis of population-based studies suggesting rates of 17% in children aged 9–12 years and 7.5% among adolescents aged 13–18 years (Kelleher *et al.*, 2012). Horwood *et al.* (2008) reported a 6-month prevalence in 11-year-old children of 13.7% for “suspected or definite” psychotic-like symptoms (the figure included in the meta-analysis by Kelleher *et al.*, 2012). This was reduced to 5.6% when only “definite” symptoms were included. While non-clinical psychotic symptoms are relatively common in children and fall in prevalence during adolescence, psychotic disorders are extremely rare in children and increase in incidence and prevalence throughout adolescence.

Clinically defined schizophrenia has an incidence of 15.2 per 100,000, point prevalence of 4 in 1000 with conspicuous geographical variations in the incidence and prevalence rates (McGrath *et al.*, 2008). While it is generally agreed that the onset of schizophrenia before the age of 12 is very rare, good, population-based incidence figures for EOS are lacking. At present, no data are available to comment on the geographical variations or time trends in the rates of EOS. Studies of clinical samples suggest that <1% of all reported cases with schizophrenia have an onset before age 10, and 4% before age 15 (Remschmidt *et al.*, 1994). Using hospital admission data of an epidemiologically defined sample, the prevalence of DSM-III schizophrenia in children and adolescents was calculated as 0.23%, with half of the prevalent cases younger than 16 years of age (Gillberg, 2000).

Sex differences

Females have a delayed onset of schizophrenia (~1.5 years) compared to males (Eranti *et al.*, 2013) and show a distinct later peak (>age 35 years). This is reflected in the epidemiology of childhood-onset cases, wherein males are over-represented in many clinical studies (Russell *et al.*, 1989). However, other studies of predominantly adolescent-onset schizophrenia have described an equal sex ratio (Werry *et al.*, 1994; Hollis, 2000a). The interpretation of these studies is complicated by the possibility of referral biases. The finding of an equal sex distribution with adolescent-onset is intriguing as it differs from the consistent male predominance (ratio 1.4:1) reported in the overall incidence of schizophrenia (McGrath *et al.*, 2008).

Genetic risk factors

Schizophrenia is very highly heritable (80%) (Gejman *et al.*, 2011), though in most patients the illness is sporadic with no family history of psychosis (Yang *et al.*, 2010). Existing genetic data suggest that multiple genetic variants of varying frequencies (common to rare variants) contribute (Sullivan *et al.*, 2012). Subgroups with strong Mendelian segregation have not been found.

Common variants

To date, the most consistent finding from schizophrenia Genome Wide Association Studies (GWAS; see Chapter 24) implicates a role for major histocompatibility complex (MHC) on chromosome 6, microRNA MIR137 (a noncoding RNA implicated in synaptic potentiation and axonal guidance signaling) (Wright *et al.*, 2013), TCF4 (a neuronal transcription factor associated with Pitt-Hopkins syndrome), CSMD1 (CUB and Sushi Multiple Domains 1, a complement cascade controlling gene), and NGRN (a calmodulin-binding protein kinase that modulates NMDA receptor signaling) (Stefansson *et al.*, 2009; Ripke *et al.*, 2011). Of note, none of the candidate genes (NRG1, COMT, DISC1, DTNBP1, BDNF, and G72 (DAOA)) implicated from pre-GWAS genetic studies has survived the rigorous approach undertaken by the GWAS. The use of an explicit polygenic model that uses a low statistical threshold in GWAS has indicated that several hundreds of common variants confer the susceptibility to develop schizophrenia, adding support to the common-disease common-variant model (Purcell *et al.*, 2009). While all the selected individual loci that survive genome-wide significance could explain only 3% of the heritability (Purcell *et al.*, 2009; Lee *et al.*, 2012), polygenic discovery sets explain up to 30% of the heritability of schizophrenia.

Rare variants

The contribution of rare variants has received significant support with the discovery of structural variations in the genome (copy number variants (CNVs); see Chapter 24). Several studies report a significant increase in the net burden of CNVs among patients with schizophrenia, compared to controls (OR = 1.15) (Stone *et al.*, 2008). A CNV deletion at 22q11.21 (associated with velocardiofacial syndrome) is present in nearly 1% of patients with schizophrenia (Ivanov *et al.*, 2003), and is one of the largest individual risk factors for the development of schizophrenia (20–25% risk), trumped only by the risk of having an identical twin with schizophrenia (Gejman *et al.*, 2011). Other replicated CNVs include deletions at 1q21.1, 2p16.3 (NRXN1) and 3q29. Unlike common variants implicated in schizophrenia, individual CNVs are associated with higher risk ratios (individual OR = 3–25), though several healthy subjects also carry a number of CNVs (Sullivan *et al.*, 2012). As a result, the overall positive predictive value of CNVs (~12%) remains much lower than that required for diagnostic clinical use (Levinson *et al.*, 2011). Most CNVs discovered so far appear nonspecific to

schizophrenia, and are seen in other disorders such as autistic spectrum disorders (ASD) or mental retardation (see Chapter 3). Such pleiotropic effects are also noted among the Single Nucleotide Polymorphisms (SNP). Pooled GWAS data from five major psychiatric disorders (schizophrenia, bipolar disorder, ASD, ADHD, and major depression) suggest that a common cross-disorder genetic risk may be conferred by intronic SNPs at 3p21, 10q24 and CACNA1C, CACNB2 genes coding for alpha-1C and beta-2 subunits of voltage-dependent calcium channels at 12p13 and 10p12, respectively (Cross-Disorder Group of the Psychiatric Genomics Consortium, 2013).

Genetic data exclusive to EOS is limited. The true familial risk of EOS is not known. But existing evidence suggests that the candidate genes originally implicated in adult onset cases (G72, DTNBP1, COMT, NRG1) may have a higher penetrance in EOS (Addington & Rapoport, 2009). In the NIMH sample EOS, a high proportion (10%) showed cytogenetic abnormalities, including 5% with 22q11 deletion (Sporn *et al.*, 2004b). Further, younger onset patients have higher net burden of CNVs compared to adult-onset cases, or parental controls (28% in EOS, 13% in parental controls, $OR = 2.6$), with a disproportionate representation of genes from signaling networks controlling neurodevelopment and synaptic function (Walsh *et al.*, 2008; Rapoport *et al.*, 2012). The rate of CNV burden is further pronounced ($\sim 53\%$) if the EOS sample is selected for the presence of speech and social or motor developmental problems (Addington & Rapoport, 2009). Interestingly, the presence of sex chromosome anomalies in EOS are significantly higher than that found in adult cases or in the general population (Addington & Rapoport, 2009). At least a portion of the hidden heritability related to sex chromosomes is not detected by current GWAS (Hickey & Bahlo, 2011).

A number of identified SNPs from schizophrenia GWAS are intronic, while the CNVs are of very large size; as a result, locating the causally important genes is challenging. Consequently, the present knowledge of causal pathways bridging the genetic loci with the observable features of schizophrenia is limited. Nevertheless, a large body of evidence indicates that the bulk of the genetic variants implicated in schizophrenia affect brain development, possibly converging on synaptic functions (Rapoport *et al.*, 2012).

Environmental risk factors

Advanced paternal age

Advanced paternal age at the time of birth has a significant association with later risk of schizophrenia, especially in sporadic cases (population attributable risk of paternal age $>30 = 10\%$), independent of maternal age, social class, family history, and birth complications (Malaspina *et al.*, 2001a). Spermatogonial stem cells undergo constant replication and in the presence of diminished DNA repair mechanisms in advanced age, the likelihood of de novo mutations is amplified (Crow, 2003).

Pregnancy and birth complications

Obstetric complications (OCs) have long been implicated as a risk factor in schizophrenia, with support from the meta-analytic literature (Cannon *et al.*, 2002), though the pooled effect is small ($OR = 2.0$). Specific OCs such as abnormal presentation and cesarean birth have been reported as more common in patients with onset of schizophrenia <22 years of age (Verdoux *et al.*, 1997) but findings are inconsistent (Ordoñez *et al.*, 2005; Margari *et al.*, 2011). Insofar as there is a significant association, it seems likely that OCs are *consequences* rather than *causes* of abnormal neurodevelopment (Goodman, 1988). This view is supported by the finding that people with schizophrenia have smaller head size at birth than controls (McGrath & Murray, 1995), which is a likely consequence of either defects in genetic control of neurodevelopment or earlier environmental factors such as viral exposure.

Role of infection/inflammation

Many studies have investigated the relationship between prenatal influenza and schizophrenia with inconsistent results from ecological studies (Selten *et al.*, 2010) though sero-epidemiological studies suggest a significant trend, especially if the exposure is in the first trimester (Brown, 2011). A twofold increase in risk of schizophrenia in offspring has been observed in association with increased maternal levels of IgG antibodies to *Toxoplasma gondii* (Mortensen *et al.*, 2007). Though the exact causal mechanism is unknown, animal models of maternal immune activation suggest cytokine-mediated disruption of neurodevelopment that expresses as postpubertal disruption in neurotransmitter functions (Meyer *et al.*, 2009). Childhood viral infections also show an association with adult schizophrenia ($RR = 2.1$), though it is unclear if this is a cause or consequence of schizophrenia-related deficits (Khandaker *et al.*, 2012).

Prenatal famine

Severe maternal intrauterine nutritional deficiency may increase the risk for schizophrenia in adult life. Evidence of a twofold increase for schizophrenia in children born to the most malnourished mothers comes from studies of the 1944–1945 Dutch Hunger Winter and the Chinese Famine of 1959–1961 (Susser *et al.*, 1996; St Clair *et al.*, 2005). Several micronutrient deficiencies including folate, iron, and vitamin D have been hypothesized to mediate this association.

Cannabis and schizophrenia

A meta-analysis of four well-conducted longitudinal population-based studies from Sweden (Swedish conscript cohort), the Netherlands (NEMESIS), and New Zealand (Dunedin and Christchurch cohorts) concluded that, at an individual level, cannabis confers an overall twofold increased risk for later schizophrenia, varying in a dose-dependent fashion (Arseneault *et al.*, 2004). In the Dunedin cohort, the association was strongest for the youngest cannabis users (after controlling

for prior psychotic symptoms) with 10.3% of the cannabis users at age 15 developing schizophreniform disorder at age 26 (Arseneault *et al.*, 2002). So far, cannabis use has not been directly implicated in EOS—possibly because of the relatively lower prevalence of cannabis use in younger adolescents and a short duration between exposure and psychotic outcome; an average delay of 7–8 years has been observed between the first exposure to cannabis and the onset of psychotic symptoms (Stefanis *et al.*, 2013). However, cannabis use is associated with an average of 2.7 years earlier onset of psychotic symptoms (Large *et al.*, 2011).

Psychosocial risks

Migration and social class

Migration and social class are both associated with variation in the incidence of schizophrenia. First- and second-generation migrants have a significantly (RR=2.7 in first generation, RR=4.5 in second generation) inflated risk of schizophrenia (Cantor-Graae & Selten, 2005), especially if immigration occurs at a younger age. The relative risk is highest in migrants from developing countries and where the majority population is black. Adjustment for social class reduces, but does not eliminate, the effects of migration. Migrants living in deprived inner cities are exposed to a range of psychosocial adversities including increased exposure to drugs, discriminatory experiences, violence, and crime. Notably, the degree of urbanicity during upbringing (March *et al.*, 2008) and living in regions with low density of members of own ethnic group (Boydell *et al.*, 2001) are also associated with elevated risk of schizophrenia, while the evidence for a link with social class is inconsistent and fraught with confounders (Brown, 2011). The mechanisms linking social adversity to psychosis are unclear—but one suggestion is that experience of social defeat and isolation increases liability to dopamine dysregulation and cognitive distortions (Broome *et al.*, 2005).

Childhood abuse and neglect

A putative link between childhood trauma and psychotic symptoms in adult life has been noted in population-based surveys (Janssen *et al.*, 2004; Bebbington *et al.*, 2011). While strong claims have been made for this link, the evidence to date remains inconclusive, with most studies supporting the link having serious methodological weaknesses (Morgan *et al.*, 2006), and the reported associations are for nonspecific psychotic symptoms rather than clinically defined schizophrenia.

Gene–environment interactions

Genotype–environment (G–E) interplay is often suspected to underlie a significant portion of schizophrenia heritability. For example, a number of genetic factors linked to schizophrenia

can increase the risk of fetal hypoxia, which can in turn increase the risk of schizophrenia (Schmidt-Kastner *et al.*, 2012). Traumatic brain injury, which is associated with an elevated risk of schizophrenia (OR=2.06), is more common in individuals with high familial loading for schizophrenia (Malaspina *et al.*, 2001b). Some of the apparent interactions may arise from genetic differences in exposure to particular environment (G–E correlations). Another aspect to consider is the epigenetic influence of environmental factors that can “instruct” (activate or silence) gene expression. Overall methylation patterns of several hundreds of genes expressed in the prefrontal cortex, including those involved in GABA and glutamatergic transmission, are abnormal in schizophrenia (Pidsley & Mill, 2011). With individual genetic loci being increasingly clarified through genome-wide searches, seeking specific G–E effects presents great promise in the near future.

Neurobiology

The concept of schizophrenia as a neurodevelopmental disorder has been a dominant explanatory model over several decades. The original notion was that of a “fixed” lesion occurring in early development but only manifesting as later psychosis following maturation (Murray & Lewis, 1987; Weinberger, 1987), or a pathological “lesion” that primarily emerges due to disturbed “late” maturational processes (Feinberg, 1982). In particular, the “late” neurodevelopmental model proposes that *excessive* synaptic and/or dendritic elimination occurring during adolescence produces aberrant neural connectivity (McGlashen & Hoffman, 2000). A third viewpoint, the neurodevelopmental “risk” model, proposes that early and/or late brain pathology acts as a risk factor rather than a sufficient cause, so that its effects can only be understood in the light of an individual’s exposure to other risk and protective factors (Hollis & Taylor, 1997). This latter formulation provides a probabilistic model of the onset of schizophrenia in which aberrant brain development is expressed primarily as neuro cognitive impairments that interact with environmental risk factors to produce psychotic symptoms.

The current notion posits that several deviant maturational trajectories in brain development beginning early in fetal life are set in motion by genetic and environmental factors, and continue to be shaped by influences that occur during developmentally critical time periods, and culminate in and continue beyond the clinical expression of schizophrenia. Aberrant brain connectivity, both at a synaptic microscale, and a larger scale involving distributed brain networks, is considered as a crucial mechanism for the manifestation of symptoms.

Cross-sectional structural changes

Cross-sectional structural neuroimaging studies of adult schizophrenia have repeatedly demonstrated a reduction in total gray matter (GM) volume, especially focussed on bilateral

insula, anterior cingulate cortex, thalamus and superior temporal cortex, irrespective of the stage of illness. While some of these changes are reflective of factors related to disease severity rather than the diagnostic status, frontoinsular and temporal changes are consistently noted in meta-analytic studies (Ellison-Wright *et al.*, 2008; Glahn *et al.*, 2008) and appear to be related to clinical symptoms such as hallucinations (Palaniyappan *et al.*, 2012), making them one of the most robust structural findings besides ventricular enlargement (Sayo *et al.*, 2012) in schizophrenia. The brain changes reported in EOS appear to be very similar to those described in adult schizophrenia, supporting the idea of an underlying neurobiological continuity (Rapoport & Gogtay, 2011). EOS patients have a higher rate of developmental brain abnormalities than controls (Nopoulos *et al.*, 1998).

Volumetric changes are associated with a number of surface anatomical properties such as thickness, surface area, and gyrification (Palaniyappan & Liddle, 2012). Increased gyral curvature and a reduction in sulcal curvature along with sulcal thinning affecting frontal, temporal and parietal lobes is noted in EOS (White *et al.*, 2003). In adolescent-onset cases, both thickness and surface area reduction have been noted in prefrontal and superior temporal cortex (Voets *et al.*, 2008; Janssen *et al.*, 2009).

Apart from changes in GM structure, diffusion tensor studies have observed significant disruption in WM integrity. The nature of WM changes are much more heterogeneous than GM changes in adults (Melonakos *et al.*, 2011) though most common changes are localized to (i) a left frontal region that involves fibers connecting frontal lobe, thalamus and cingulate gyrus and (ii) a left temporal region that involves fibers connecting frontal lobe, insula, hippocampus–amygdala, temporal and

occipital lobe (Ellison-Wright & Bullmore, 2009). In EOS, there is a more widespread, albeit less consistent, reduction in WM integrity (Samartzis *et al.*, 2014). Along with GM changes, the disruptions in WM integrity add a strong case for the existence of structural dysconnectivity in schizophrenia.

Progressive structural changes

There is evidence of progressive ventricular enlargement and volume reductions after the onset of schizophrenia affecting the whole brain, with frontal lobe showing somewhat greater reduction in EOS (Kempton *et al.*, 2010; Olabi *et al.*, 2011). Significant insights have been gained from the NIMH EOS cohort (see Figure 57.1). Progressive GM reduction of comparable magnitude to the EOS cohort has also been noted in the first 2 years after the onset of illness in adolescents with schizophrenia (Arango *et al.*, 2012). At present, it is difficult to distinguish if any of the progressive morphometric changes are due to antipsychotic medications, though this is suggested by long-term follow up of adult samples (Ho *et al.*, 2011).

Progressive changes do not appear to be triggered entirely by the onset of illness; specific changes precede the onset (Pantelis *et al.*, 2003). Meta-analysis of studies comparing high-risk individuals who later develop psychosis from high-risk individuals without this transition indicates a consistent reduction in prefrontal, insular, cingulate, and cerebellar volumes before the onset of psychosis (Fusar-Poli *et al.*, 2011). In particular progressive changes in superior temporal and frontoinsular regions appear to predict the emergence of psychosis in those at a high risk (Takahashi *et al.*, 2009a, b) and the surface anatomical development of these regions continue to deviate in the initial

Figure 57.1 Summary of key gray matter structural changes reported from NIMH EOS sample (Rapoport & Gogtay, 2011). In addition, ventricular enlargement at baseline and slower growth rates of (especially right hemispheric) white matter are also noted. COS: Childhood-onset schizophrenia.

stages of schizophrenia in adolescents (Palaniyappan *et al.*, 2013).

Present evidence suggests that a disruption of the developmental trajectories during the critical periods preceding and immediately after the onset of illness contribute to the diverse changes in the GM structure that characterize schizophrenia (Figure 57.1).

Functional imaging

A consistent picture has emerged from a group of task-based functional magnetic resonance imaging (fMRI) studies that suggests that patients show inefficiency in recruiting brain regions when engaging in specific cognitive tasks. This is most apparent in tasks that require prefrontal recruitment, wherein increased recruitment of brain regions often not directly relevant to the cognitive task (e.g., increased recruitment of medial frontal regions during executive tasks) is notable alongside a significant reduction in the dorsolateral prefrontal recruitment when the task demands increase further (Glahn *et al.*, 2005). In the absence of external task demands ("resting state"), patients show abnormal time-based correlations among brain regions that form large-scale brain networks. This dysconnectivity is observed in both within-network and cross-network interactions (Pettersson-Yeo *et al.*, 2011), and are also noted in EOS (Alexander-Bloch *et al.*, 2010; Zhou *et al.*, 2010).

Oscillatory activity is thought to be a fundamental aspect of cortical neuronal coordination. A number of studies suggest that synchronous oscillations in the gamma range (30–80 Hz) are abnormal in patients, and this may be linked to the deficits in prefrontal GABAergic interneurons (Uhlhaas & Singer, 2010). In EOS, abnormalities in evoked oscillatory activity have been noted, especially in the theta and gamma frequencies (Wilson *et al.*, 2008; Haenschel *et al.*, 2009). Adolescence appears to be a crucial period for oscillation-related cortical plasticity (Uhlhaas *et al.*, 2009). The emergence of novel methods such as MEG to study the oscillatory activity has the potential to study the moderating effect of developmental changes on the various stages of development of schizophrenia.

Neuropathology

The prominent neuropathology in schizophrenia involves a region-specific (dorsolateral prefrontal cortex, layer 3 pyramidal cells) reduction in dendritic spines and synapses with increased neuronal density and decreased intraneuronal space (Glantz & Lewis, 2000). Parvalbumin expressing GABAergic interneurons show the most consistent and substantial deficits in the frontal cortex. However, early postmortem findings of aberrant neuronal migration have not been replicated (Beasley *et al.*, 2002); so the developmental timing of these core neuropathological features remains unclear.

A number of postmortem studies in schizophrenia observe a lack of a typical glial response expected in the presence of an explicit pathological insult (Schnieder & Dwork, 2011), but several lines of evidence converge to suggest abnormalities in the

metabolic and synthetic activities of the glial cells such as abnormal glutamate homeostasis and myelin production (Katsel *et al.*, 2011; Takahashi *et al.*, 2011). Glial pathology is an active area of investigation at present.

There is a recent resurgence of interest in the links between inflammation and schizophrenia, as discussed in the earlier sections. Circulating cytokine levels are altered in patients with schizophrenia. Interleukin (IL)-1 β , IL-6, and transforming growth factor- β are elevated during relapses and also during first episode but are normalized with antipsychotic treatment. In contrast, certain cytokines such as IL-12, interferon- γ , tumor necrosis factor- α , and soluble IL-2 receptor remain elevated despite antipsychotic treatment (Miller *et al.*, 2011). Though there is no direct evidence implicating immunological insults in this context, two PET studies that have noted increased microglial activation (van Berckel *et al.*, 2008; Doorduyn *et al.*, 2009) suggest that focal neuro inflammation is a feature of schizophrenia, at least in a subset of patients. In line with this, early treatment trials of both anti-inflammatory (e.g., NSAIDs as add-on treatments (Sommer *et al.*, 2012)) and antibiotic agents (e.g., minocycline for negative symptoms (Chaudhry *et al.*, 2012)) have been found to be promising, though these beneficial effects could be mediated via mechanisms unrelated to inflammation.

Neurochemistry

Schizophrenia is an illness that affects almost all of the major neurotransmitter systems. At present, more is known about aberrations in the dopaminergic system than in other neurotransmitters; striatal presynaptic dopamine synthetic capacity is increased at least in a subset of patients with schizophrenia from an early stage of illness (Howes *et al.*, 2012). Glutamate/GABA abnormalities are also being increasingly appreciated from post-mortem and magnetic resonance spectroscopy (MRS) studies. An excess of glutamate in the medial prefrontal cortex is noted in early stages of schizophrenia, though in later stages, reduced levels are noted (Marsman *et al.*, 2011). GABA/glutamatergic system is a strong suspect for mediating cognitive dysfunction in schizophrenia, providing a promising therapeutic target for a symptom domain that is clearly resistant to dopaminergic interventions.

Neuropsychology of schizophrenia

The pattern of cognitive deficits

Cognitive deficits form a core feature linked to functional outcome and recovery. A prominent aspect is the presence of a broad performance deficit. Patients with EOS show notable reduction in IQ, with nearly one-third showing IQ levels below 70 in some studies (Hollis, 2000b). This deficit does not appear to be progressive, but stabilizes after the early stage of the illness (Gochman *et al.*, 2005). The largest effect size of cognitive deficits reported in EOS so far pertain to the domain of executive

functions (Rhinewine *et al.*, 2005), and along with processing speed deficits, explain a large portion of the variance in everyday living skills in patients (Puig *et al.*, 2012). A reduction in processing speed is often claimed to be the central factor explaining a number of other cognitive abnormalities in patients (Dickinson *et al.*, 2007). Verbal memory deficits are also prominent, with deficits somewhat more pronounced in EOS cases (Kravariti *et al.*, 2003). Despite the widespread nature of cognitive deficits, “over learned” rote language and simple perceptual skills are unimpaired in EOS. These observations are consistent with the notion that both a broad deficit affecting various cognitive domains and specific deficits affecting some but not all cognitive domains are present in schizophrenia (Gold *et al.*, 2009).

The course of cognitive deficits

When do these cognitive deficits appear? Dunedin cohort participants (observed from the age of 3–32), who developed adult schizophrenia, exhibited static cognitive deficits that emerge early and remain stable on tests indexing verbal and visual knowledge acquisition, reasoning, and conceptualization. In contrast, a developmental lag pattern (slower gain relative to healthy comparison subjects) was noted on tests indexing processing speed, attention, visual-spatial problem solving ability, and working memory. Interestingly, there was no evidence of progressive cognitive deterioration in children destined to develop schizophrenia at a later stage (Reichenberg *et al.*, 2010).

Do these deficits show progressive deterioration after illness onset? A decline in IQ from childhood through adolescence preceding the onset of schizophrenia in adult life has been reported in a large population-based cohort (Reichenberg *et al.*, 2005). There is some tentative evidence for a small decline in IQ following the onset of EOS (Alaghband-Rad *et al.*, 1995), followed by a stabilization of cognitive function (Gochman *et al.*, 2005). In adolescent-onset cases, while several cognitive functions

remain stable, a decline in verbal memory (Frangou *et al.*, 2008; Øie *et al.*, 2010), along with lack of age-related improvement in learning and processing speed (Øie *et al.*, 2010), is seen. This longitudinal pattern appears to be different from the changes seen in children with ADHD (Øie *et al.*, 2010). However, another follow-up study did not find evidence for declining verbal memory over a 2-year period (Cervellione *et al.*, 2007).

In summary, patients with EOS show consistent impairments in IQ, processing speed, verbal memory and measures of attention, albeit with notable heterogeneity. A number of these deficits show a well-established relationship between younger age of onset and the severity of cognitive impairment (Rajji *et al.*, 2009). Overall, there is little evidence for persisting progressive decline in any of the specific cognitive domains after the illness onset (Table 57.1).

Assessment

The assessment of a child or adolescent with possible schizophrenia should include a detailed history, mental status, risk assessment (including self-harm and suicidal risk) and physical examination (see Chapters 32 and 35). In addition, a baseline psychometric assessment is desirable. A detailed understanding of specific cognitive deficits in individual cases can be particularly helpful in guiding education and rehabilitation. In the physical examination, particular attention should be given to detecting clinical features that may betray an underlying genetic syndrome (e.g., 22q11 velocardiofacial syndrome). The neurological examination should focus on abnormal involuntary movements and other signs of extrapyramidal dysfunction. Spontaneous, abnormal involuntary movements have been detected in a proportion of drug-naïve first-episode schizophrenic or schizophreniform

Table 57.1 Comparison of early-onset and adult-onset schizophrenia.

Early onset schizophrenia versus adult onset schizophrenia	
Epidemiology	Clinically defined early-onset schizophrenia is rare (<4% of all cases) though higher rates of self-reported psychotic symptoms occur in children and adolescents.
Neurocognition	More severe impairments in association with earlier onset. No significant variations in the cognitive domains affected (IQ, processing speed, verbal memory, and executive functions show largest deficits in both groups).
Brain structure	Spatial distribution of defects comparable in both groups. More prominent progressive changes in early onset group.
Genetics	Higher penetrance of candidate genes, higher burden of structural variations, and sex chromosome anomalies in early-onset group.
Risk factors	Most environmental/psychosocial risk factors common across the two groups, though the proportion of overall risk attributable to specific factors vary in accordance with age-specific prevalence rates for the risk factors (e.g., cannabis use is less frequent in children).
Phenomenology	Clinical symptoms common across the two groups. No unique features noted in the early-onset group, though more insidious onset, negative symptoms, hallucinations in different modalities, and a fewer systematized delusions are reported.
Course	More chronic course associated with earlier onset.
Outcome	Poorer long-term functional outcome associated with earlier onset.

patients, as well as in those receiving typical antipsychotics (Gervin *et al.*, 1998).

Developmental issues

The cognitive level of the child will influence its ability to understand and express complex psychotic symptoms such as passivity phenomena, thought alienation, and hallucinations. In younger children careful distinctions have to be made between developmental immaturity and psychopathology. For example, distinguishing true hallucinations from normal subjective phenomena like dreams and communication with imaginary friends may be difficult for young children. Developmental maturation can also affect the localization of hallucinations in space. Internal localization of hallucinations is more common in younger children and makes these experiences more difficult to subjectively differentiate from inner speech or thoughts (Garraida, 1984). Formal thought disorder may also appear very similar to the pattern of illogical thinking and loose associations seen in children with immature language development. Negative symptoms can appear very similar to non-psychotic language and social impairments and can also be easily confused with anhedonia and depression.

Differential diagnosis

Psychotic symptoms in children and adolescence are diagnostically nonspecific, occurring in a wide range of functional psychiatric and organic brain disorders. A summary of physical investigations that may be considered in children and adolescents with suspected schizophrenia is listed in Table 57.2. Referral for a neurological opinion is recommended if neurodegenerative disorder is suspected (see below).

Affective and “atypical” psychoses

Because significant affective symptoms also occur in about one-third of first-episode patients with schizophrenia, it may be

impossible to make a definitive diagnosis on the basis of a single cross-sectional assessment. In DSM-5 the distinction between schizophrenia and affective psychoses is determined by the relative predominance and temporal overlap of psychotic symptoms (hallucinations and delusions) and affective symptoms (elevated or depressed mood). Given the difficulty in applying these rules with any precision, there is a need to identify other features to distinguish between schizophrenia and affective psychoses. Irrespective of the presence of affective symptoms, the most discriminating symptoms of schizophrenia are an insidious onset and the presence of negative symptoms (Hollis, 1999). Similarly, complete remission from a first psychotic episode within 6 months of onset is the best predictor of a diagnosis of affective psychosis (Hollis, 1999).

Autistic spectrum and developmental language disorders

Some children with ASD have social and cognitive impairments that overlap closely with the premorbid phenotype described in schizophrenia (see Chapter 51). While children on the autistic spectrum can develop psychotic symptoms in adolescence (Volkmar & Cohen, 1991), adult follow-up suggests no increased risk of schizophrenia (Hutton *et al.*, 2008). However, an increased risk for psychosis has been noted in the adult follow-up of childhood developmental receptive language disorders (Clegg *et al.*, 2005). In the NIMH EOS sample, 19 cases (25%) had a lifetime diagnosis of ASD; 1 had autism, two had Asperger's Syndrome and 16 had PDD-NOS (Sporn *et al.*, 2004a). The EOS-ASD subgroup did not differ from the rest of the EOS sample on a range of measures including age of onset, IQ, response to medications and familial schizotypy. However, the rate of cortical GM loss was greater in the ASD group. While some children on the autistic spectrum can show a clear progression into classic schizophrenia, others show a more episodic

Table 57.2 Physical investigations in child and adolescent-onset psychoses.

Investigation	Target disorder
Urine drug screen	Drug-related psychosis (amphetamines, ecstasy, cocaine, LSD and other psychoactive compounds)
EEG	Complex partial seizures/TLE
MRI brain scan	Ventricular enlargement, structural brain anomalies (e.g., cavum septum pellucidum) Enlarged caudate (typical antipsychotics) Demyelination (metachromatic leukodystrophy) Hypodense basal ganglia (Wilson's disease)
Serum copper and caeruloplasmin/Urinary copper	Wilson's disease
Arylsulfatase A (white blood cell)	Metachromatic leukodystrophy
Karyotype/cytogenetics (FISH)	Sex chromosome aneuploidies, velocardiofacial syndrome (22q11 microdeletion)
Anti-NMDA IgG antibodies	NMDA receptor encephalitis (acute psychosis with headaches, speech disorder, and dyskinesia)

EEG, electroencephalogram; FISH, fluorescent *in situ* hybridization; LSD, lysergic acid diethylamine; MRI, magnetic resonance imaging; TLE, temporal lobe epilepsy; NMDA, *N*-methyl D-aspartate.

pattern of psychotic symptoms without the progressive decline in social functioning and negative symptoms characteristic of EOS. Often it is possible to distinguish between schizophrenia and ASD only by taking a careful developmental history that details the age of onset and pattern of autistic impairments in communication, social reciprocity, and interests/behaviors.

Multidimensionally impaired syndrome

“Multidimensionally impaired (MDI) syndrome” is a label applied to children who have brief, transient, psychotic symptoms, emotional lability, poor interpersonal skills, normal social skills, and multiple deficits in information processing (Kumra *et al.*, 1998a). The diagnostic status of this group remains to be fully resolved (see discussion of ARMS). Short-term follow-up suggests that they do not develop full-blown schizophrenic psychosis. However, they have an increased risk of schizophrenia-spectrum disorders among first-degree relatives and the neurobiological findings (e.g., brain morphology) are similar to those noted in EOS (Kumra *et al.*, 1998a).

Epilepsy

Psychotic symptoms can occur in temporal and frontal lobe partial seizures. A careful history is usually sufficient to reveal an aura followed by clouding of consciousness and the sudden onset of brief ictal psychotic phenomena accompanied often by anxiety, fear, derealization, or depersonalization. However, longer lasting psychoses associated with epilepsy can occur in clear consciousness during postictal or interictal periods (Sachdev, 1998). In epileptic psychoses, hallucinations, disorganized behavior and persecutory delusions predominate, while negative symptoms are rare. Children with complex partial seizures may also have increased illogical thinking and use fewer linguistic-cohesive devices which can resemble formal thought disorder (Caplan *et al.*, 1992).

Epilepsy and schizophrenia may co-occur in the same individual, so that the diagnoses are not mutually exclusive. The onset of epilepsy almost always precedes psychosis unless seizures are secondary to antipsychotic medication. In a long-term follow-up of 100 children with temporal lobe epilepsy, 10% developed schizophrenia in adult life (Lindsay *et al.*, 1979). An EEG should be performed if a seizure disorder is considered in the differential diagnosis or arises as a side effect of antipsychotic treatment. Ambulatory EEG monitoring and telemetry with event recording may be required if the diagnosis remains in doubt.

Neurodegenerative disorders

Rare neurodegenerative disorders with onset in late childhood and adolescence can mimic schizophrenia. The most important examples are Wilson's disease (hepato-lenticular degeneration) and metachromatic leukodystrophy. These disorders usually involve significant extrapyramidal symptoms (e.g., tremor, dystonia, and bradykinesia) or other motor abnormalities (e.g., unsteady gait) and a progressive loss of skills (dementia) that can aid the distinction from schizophrenia.

Suspicion of a neurodegenerative disorder is one of the clearest indications for brain magnetic resonance imaging (MRI) in adolescent psychoses. Adolescents with schizophrenia show relative GM reduction with white matter (WM) sparing. In contrast, metachromatic leukodystrophy is characterized by frontal and occipital WM destruction and demyelination. In Wilson's disease, hypodense areas are seen in the basal ganglia, together with cortical atrophy and ventricular dilatation. The pathognomonic Kayser–Fleisher ring in Wilson's disease begins as a greenish-brown crescent-shaped deposit in the cornea above the pupil (this is most easily seen during slit lamp examination). In Wilson's disease there is increased urinary copper excretion, and reduced serum copper and serum caeruloplasmin levels. The biochemical marker for metachromatic leukodystrophy is reduced arylsulfatase-A (ASA) activity in white blood cells. This enzyme deficiency results in a deposition of excess sulfatides in many tissues including the central nervous system (CNS).

Drug psychoses

Illicit drug use is increasingly common among young people, so the frequent co-occurrence of drug use and psychosis is to be expected. Psychotic symptoms can occur as a direct pharmacological effect of intoxication with stimulants, hallucinogens, cannabis, and ketamine. The psychotic symptoms associated with drug intoxication are usually short-lived and resolve within a few days of abstinence from the drug. These drugs can have surprisingly long half-lives with cannabinoids still measurable up to 6 weeks after a single dose. Psychotic symptoms in the form of “flashbacks” can also occur after cessation from chronic cannabis and lysergic acid diethylamide (LSD) abuse. These phenomena are similar to alcoholic hallucinosis and typically involve transient, vivid, auditory hallucinations occurring in clear consciousness.

Other investigations

Whether any physical investigations should be viewed as routine is debatable. However, it is usual to obtain a full blood count and biochemistry including liver and thyroid function and a drug screen. The high yield of cytogenetic abnormalities reported in EOS (Nicholson *et al.*, 1999) suggest the value of cytogenetic testing including karyotyping for sex chromosome aneuploidies and fluorescent *in situ* hybridization (FISH) for 22q11DS (velocardiofacial syndrome).

At present the clinical value of a structural MRI scan lies in detecting suspected underlying brain disorders rather than being of diagnostic value in schizophrenia. However, with the use of sophisticated statistical approaches that enable individual-level classification (e.g., machine learning), structural MRI is increasingly being appreciated as a tool with a promise to become a part of regular diagnostic workup for psychosis in the near future.

Assessment interviews and rating scales

The DSM and ICD definitions of schizophrenia do not provide symptom definitions but structured diagnostic

investigator-based interviews that cover child and adolescent psychotic disorders (see Chapter 33) have detailed glossaries that can be particularly useful.

Rating scales give quantitative measures of psychopathology and functional impairment. Scales to assess psychotic symptoms include the Scale for Assessment of Positive Symptoms (SAPS) (Andreasen, 1984), the Scale for Assessment of Negative Symptoms (SANS) (Andreasen, 1983), and the Positive and Negative Syndrome Scale (PANSS) (Kay *et al.*, 1987). The 30-item Kiddie-PANSS (Positive and Negative Syndrome Scale) has been developed for use in children and adolescents, and contains three subscales: positive syndrome, negative syndrome, and general psychopathology (Fields *et al.*, 1994). The Children's Global Assessment Scale (C-GAS) provides a rating of functional impairment on a 0–100 scale (Shaffer *et al.*, 1983). These scales can be used to record the longitudinal course of illness and treatment response. The Kiddie Formal Thought Disorder Story Game and Kiddie Formal Thought Disorder Scale (Caplan *et al.*, 1989) are research instruments produced for the assessment of thought disorder in children. Assessments of extrapyramidal symptoms and involuntary movements can be made using the Abnormal Involuntary Movements Scale (AIMS) (Rapoport *et al.*, 1985) and the Simpson–Angus Neurological Rating Scale (Simpson & Angus, 1970).

Treatment approaches

General principles

While antipsychotic drugs remain the cornerstone of treatment in child and adolescent schizophrenia, all young patients with schizophrenia require a multimodal treatment package that includes pharmacotherapy, family and individual counseling, education about the illness, and provision to meet social and educational needs (National Institute for Health and Care Excellence (NICE), 2013).

Interventions targeting “at risk mental states” (ARMS)

Recent studies have examined the feasibility of detecting and treating individuals with “ARMS” (see above) to prevent transition to psychosis. To date, there have been nine randomized controlled trials (RCTs) in ARMS, which have reported findings regarding prevention or delay of transition to psychosis in young people. Stafford *et al.* (2013) reported a meta-analysis of those studies, using antipsychotic medication and/or CBT or complex psychosocial interventions. Risperidone and olanzapine were no more effective than a psychological intervention or placebo in preventing transition to psychosis or in reducing psychotic symptoms. Furthermore, olanzapine treatment resulted in significant weight gain. In contrast, CBT reduced the rate of transition to psychosis at 12 months relative to supportive counselling (RR 0.54), but did not significantly improve psychosocial functioning (Stafford *et al.*, 2013). Amminger *et al.*

(2010) reported a 12-week RCT in which intake of omega-3 polyunsaturated fatty acids resulted in a significantly lower transition rate compared to placebo. At 12-month follow-up, 2 of 41 individuals (4.9%) in the omega-3 treatment group developed psychosis compared with 11 of 40 (27.5%) on placebo. There was also a significant reduction in positive and negative symptoms and improved general functioning.

Based on this evidence, the UK NICE clinical guideline for schizophrenia and psychosis in children and young people (CG155) recommended that antipsychotic medication should not be used in young people with transient or attenuated psychotic symptoms with the aim of preventing transition to psychosis (NICE, 2013). The NICE Guideline supports the use of psychosocial interventions (family intervention and/or individual CBT) in children and young people with transient or attenuated psychotic symptoms (subthreshold for a diagnosis of schizophrenia or psychosis), as well as evidence-based treatments targeted at associated anxiety disorders, depression, emerging personality disorder, or substance misuse.

Treatments for schizophrenia and psychosis

Pharmacological

While the efficacy of antipsychotics is broadly similar in children, young people, and adults, the young show a greater sensitivity to a range of antipsychotic-related adverse events, including extrapyramidal side effects (EPS), treatment resistance with traditional antipsychotics (Kumra *et al.*, 1998b), and weight gain, obesity, and metabolic syndrome with the newer atypical antipsychotics (Correll *et al.*, 2009). The pharmacology of antipsychotic drugs and management of adverse effects is discussed in Chapter 43.

Although the number of RCTs of antipsychotics in children and young people (<18 years) with schizophrenia remains small, in recent years there have been trials reported for aripiprazole (Findling *et al.*, 2008), risperidone (Haas *et al.*, 2009), olanzapine (Kryzhanovskaya *et al.*, 2009), and paliperidone (Singh *et al.*, 2011). Taken together, antipsychotics show a small but significant effect (ES = 0.3) in reducing psychotic symptoms (NICE, 2013). While antipsychotics do not differ significantly in terms of efficacy, differences in side effects are notable; weight gain is greatest with olanzapine (with up to 8 kg gain reported in the first 12 weeks of treatment), intermediate with clozapine, quetiapine, and risperidone and least with aripiprazole (Correll *et al.*, 2009). EPS are greater with “typical” antipsychotics such as haloperidol and higher dose (>4 mg) risperidone than with quetiapine or olanzapine. Aripiprazole may cause akathisia at higher doses. Sedation is greater with olanzapine, clozapine, quetiapine, and haloperidol than with risperidone (Toren *et al.*, 2004) and aripiprazole. Hyperprolactinaemia is greatest with risperidone, amisulpride, and haloperidol and least with quetiapine and aripiprazole (aripiprazole may lower prolactin levels from baseline).

Clozapine has been shown in randomized double blind head-to-head trials to be superior to haloperidol (Kumra *et al.*,

1996) and olanzapine (Shaw *et al.*, 2006) for EOS. Clozapine's use is restricted under license in the United Kingdom to treatment-resistant schizophrenia defined as follows: (i) nonresponse with at least two antipsychotics (drawn from different classes and at least one being an atypical) each used for at least 4–6 weeks, and/or (ii) significant adverse effects with conventional antipsychotics. Adverse effects of clozapine include weight gain, sedation, hypersalivation, and reduced seizure threshold. The risk of blood dyscrasias on clozapine is effectively managed by mandatory routine blood monitoring.

Baseline investigations and monitoring

Before starting treatment with antipsychotic medication, a physical examination should include height, weight (BMI, body mass index), and cardiovascular system examination, including pulse and blood pressure, and a neurological examination for evidence of abnormal movements. Baseline laboratory investigations include full blood count, liver function and electrolytes, prolactin, fasting blood glucose, HbA_{1C}, and plasma lipids. The NICE (2013) guidance recommends that weight be measured weekly for the first 6 weeks of treatment, again at 12 weeks and thereafter 6-monthly and pulse, blood pressure, prolactin, fasting blood glucose, HbA_{1C} and lipids should be repeated at 12 weeks and thereafter 6-monthly.

Pharmacological interventions: summary

Choice of antipsychotic medication is determined primarily by side effect profile, given broadly similar efficacy of antipsychotics. The greater sensitivity of children and young people to adverse effects of antipsychotics means that the benefit to risk ratio may be lower than in adults. Drug choice should be a collaborative exercise, tailored to the needs and preferences of the young person and the family. In children and young people naive to antipsychotics, atypical drugs are preferred as they minimize the risk of acute dystonic reactions that are common with high-potency conventional antipsychotics (e.g., haloperidol) in young people. Antipsychotics should be started below the usual dose range for adults and titrated slowly upwards against clinical response and side effects to determine the minimum effective dose. Short-term use of benzodiazepines (e.g., lorazepam) is preferable to high-dose antipsychotics in the management of severe behavioral disturbance associated in acute psychosis. The recommended order of treatment for first-episode schizophrenia in children and adolescents is: atypical as first line; if inadequate response, change to a different atypical or conventional antipsychotic; if response is still inadequate or side effects are intolerable, then initiate clozapine. Antipsychotic medication is usually maintained for at least 2 years after a first episode of schizophrenia, with formal review of medication, including physical health, conducted at least annually (NICE, 2013).

Psychosocial intervention

Cognitive behavior therapy (CBT)

In contrast to the adult literature, there is a much smaller and weaker evidence base to support CBT and family interventions in EOS. The NICE Guideline for schizophrenia and psychosis (NICE, 2013) identified only six RCTs ($N=460$) comparing individual CBT with a control intervention in children and young people with mean age 25 years and younger (Power *et al.*, 2003; Haddock *et al.*, 2006; Mak *et al.*, 2007; Jackson *et al.*, 2008; Jackson *et al.*, 2009; Edwards *et al.*, 2011). There were no studies of CBT where all participants were <18 years. Three of the studies (Power *et al.*, 2003; Jackson *et al.*, 2008; Edwards *et al.*, 2011) were conducted in a specialist EPPIC in Australia. All participants in these studies received the relatively intensive “treatment as usual” (TAU) offered by EPPIC. Taken together, these studies found no benefit of CBT compared to control interventions for psychotic symptoms (Jackson *et al.*, 2008; Edwards *et al.*, 2011), depression/suicidality (Power *et al.*, 2003; Edwards *et al.*, 2011), or social adjustment (Jackson *et al.*, 2008). Haddock *et al.* (2006) reported an interaction with age, so that for young people <age 21, results were better for supportive counselling compared to CBT or wait-list control, while in contrast, for young people age >21, outcomes were superior for CBT.

These results are intriguing as they suggest that for young people (<21 years) CBT may be relatively less effective as an intervention for schizophrenia than in adults. Reasons for this apparent lack of benefit of CBT in EOS may include (i) methodological weaknesses and small numbers of young people included in these studies and (ii) the early phase of the illness and primary outcomes chosen. The strongest evidence for CBT in adults with schizophrenia is for treatment-resistant positive symptoms (Turkington & Kingdon, 2000), while in trials in young people, CBT has been evaluated in the acute phase of the illness. (iii) Greater cognitive impairments and/or illness severity in young people may moderate the effectiveness of unmodified CBT interventions developed for adults with schizophrenia.

Family intervention

The UK NICE Guideline for schizophrenia and psychosis in children and young people identified only two RCTs ($N=158$) comparing family intervention with an active control in young people aged <25 years. Both studies were conducted with young people in remission for psychosis and compared family CBT with individual CBT (Linszen *et al.*, 1996; Gleeson *et al.*, 2009). Family intervention was no more effective than an active control in reducing the number of participants who relapsed. In summary, family intervention in young people with schizophrenia fails to show the clear benefits for relapse prevention (Number Needed to Treat of 4; see Chapter 14) reported in adults (NICE, 2013).

Psychosocial interventions: summary

For both CBT and family interventions, the evidence from a small number of RCTs in young people (mean age <age 25), so far fails to replicate benefits seen from the much larger body of evidence in adults. The NICE (2013) guideline concluded that there were insufficient good quality studies in children and young people to draw firm clinical recommendations from this evidence base. NICE reasoned that as there was no *a priori* reason to treat EOS differently from adults, psychosocial interventions (family intervention and/or individual CBT) that have been shown to be effective in adults should be offered in conjunction with antipsychotic medication to children and young people. However, it is recommended that CBT manuals developed for adults should be adapted for use with children and young people.

Organization of treatment services

From the early 2000s onwards in the United Kingdom and other Western countries, Early Intervention in Psychosis (EIP) services covering ages 14–35 have been developed that provide rapid assessment and intervention for the first 3 years following onset of psychosis. Children and adolescents under the age of 18 may be assessed and treated either in a generic child and adolescent mental health service (CAMHS) or in a 14–35 EIP service. The drawbacks of these parallel mental health services for children and young people are that generic CAMHS may lack specific psychosis expertise and the range of interventions typically found in EIP services. Generic CAMHS services are usually unable to provide the mix of assertive outreach, early intervention and crisis resolution services that have developed in EIP teams. Meanwhile, EIP services may lack CAMHS expertise around developmental issues, differential diagnosis of neurodevelopmental disorders, and in delivering family interventions.

The UK NICE (2013) guideline supported rapid referral of children and young people with suspected psychosis from primary care to a consultant psychiatrist with training in child and adolescent mental health (either in CAMHS or an EIP service). The assessment and accurate diagnosis of psychosis and schizophrenia in children and young people can be complex and clinically challenging because it has to take into account developmental factors and the potential differential diagnoses and comorbid conditions arising in children and young people, which differ from adults. In the United Kingdom, CAMHS input to EIP teams is limited and models of joint working have been proposed (Tiffin & Hudson, 2007). There is emerging evidence that the EIP model of working has health economic benefits compared to generic CAMHS, principally because of reduced in-patient utilization for psychosis treatment (McCrone *et al.*, 2013). Ideally, CAMHS trained staff should be embedded in EIP services and take the lead for assessment and management of young people between the ages of 14 and 17 (NICE, 2013).

Conclusions

There has been a dramatic growth in our understanding of the neurobiological underpinnings and clinical course of schizophrenia presenting in childhood and adolescence. Recent findings from genetics suggest pleiotropic mechanisms underlie the dimensional overlaps between neurodevelopmental disorders, rather than finding specific genes for different disorders. Neuroimaging research has uncovered the importance of dysfunctional coordination of brain networks. It is now clear that adult-based diagnostic criteria have validity in this age group and the disorder has clinical and neurobiological continuity with schizophrenia in adults. EOS is a severe variant of the adult disorder associated with greater premorbid impairment, a higher familial risk, and more severe clinical course and poorer outcome. The poor outcome of children and adolescents with schizophrenia has highlighted the need for more trials recruiting young people <18 years to increase the evidence base for effective early intervention strategies and treatments for young people with psychosis and schizophrenia.

B: Emotional

CHAPTER 58

Disorders of attachment and social engagement related to deprivation

Charles H. Zeanah and Anna T. Smyke

Department of Psychiatry and Behavioral Sciences, Tulane University School of Medicine, New Orleans, LA, USA

Although attachment disorders have been described in the literature for nearly 75 years and have been defined by specified criteria in psychiatric nosologies for more than three decades, they have been studied systematically only recently. More than 90% of the research related to understanding attachment disorders has appeared in the past decade. Controversies remain, but there is a growing consensus at least about the manifestations of the disorders in early childhood.

The purpose of this chapter is to review what is known about reactive attachment disorder (RAD) and disinhibited social engagement disorder (DSED), especially in the context of severe deprivation, and in light of emerging research. Although different or more expanded versions of attachment disorders have been proposed by some (Zeanah & Boris, 2000; van IJzendoorn & Bakermans-Kranenburg, 2002; Minnis *et al.*, 2006) these alternative approaches are less well studied, and we have focused our review primarily on the traditional conceptualization of the disorders, as defined in contemporary nosologies.

Definitions

The term “attachment” itself has been used variably to refer to different constructs, and this has led to confusion in the literature. Bowlby, who developed attachment theory, asserted that attachment referred to the young child’s strong disposition “to seek proximity to and contact with a specific figure and to do so in certain situations, notably when ... frightened, tired, or ill. The disposition to behave in this way is an attribute of the child, an attribute which changes only slowly over time and which is unaffected by the situation of the moment” (Bowlby, 1982, p. 371). Therefore, we describe attachment as a tendency for human infants to seek comfort, support, nurturance, and protection preferentially from one or more caregivers. This is

sometimes referred to as “focused,” “preferred,” “selective,” or “discriminated” attachment between child and parent. Because the parent–child attachment relationship is asymmetrical, the young child is the seeker and the adult caregiver/parent is the provider in the attachment relationship. Therefore, it is the parent’s job to support the child and not vice versa (see also Chapter 6).

The tendency to approach an adult is believed to be stimulated by increased levels of negative arousal, accompanied by emotions such as distress, fear, frustration, and hurt. These increase the child’s motivation to seek support and comfort from someone they have learned is reliably available to provide it. In attachment terms, the child seeks and receives a feeling of security from the physical closeness and emotional availability of a trusted adult caregiver.

A significant challenge to the definition of disordered attachment, however, is the very ubiquity of attachment in young children. Under species-typical rearing conditions, virtually all children form attachments to their caregivers. In children with clinical disturbances of a variety of types, attachment formation or expression may be compromised. Thus, an important question is when the disturbed attachment is the primary problem, in which case it comprises an attachment disorder, and when disturbed attachment is merely an associated feature of some other disorder. An appreciation of the development of attachment under usual circumstances provides a useful foundation from which to begin to answer this question.

Development of attachment

Parents’ affiliative feelings for their infants often begin prenatally. Studies have indicated that parents are willing to describe a sense of who the baby is and assert that they have a relationship with

Rutter’s Child and Adolescent Psychiatry, Sixth Edition.

the baby even before the baby is born (Zeanah *et al.*, 1985; Benoit *et al.*, 1997). The birth of the infant usually intensifies feelings of affection, and the newborn's physical attributes, called "babyishness" (Lorenz 1943), are known to draw the attention, interest, and even affection of adults (Stern, 1977).

Although most parents report feeling attached at birth or even before, infants are not born attached to their caregivers. The tendency for selective seeking of comfort is not apparent in the first 6 months after birth. Instead, attachment emerges gradually over the first year of life. By 2–3 months of age, social engagement behaviors emerge, with responsive smiling and cooing and more sustained eye-to-eye contact between infants and adult caregivers. Of note, these behaviors are readily displayed toward both familiar and unfamiliar adults until about 7 or 8 months of age. Two new infant behaviors become apparent at that point: stranger wariness and separation protest. Stranger wariness describes an apparent discomfort with unfamiliar adults and preferentially turning to those caregivers the child knows and trusts. Separation protest refers to the infant's tendency to protest separation from familiar caregivers. Although individual differences in the intensity and expression of these behaviors are clear, they may be considered universal. When these behaviors appear, the infant is said to be "attached" to one or more caregivers. The phases in the development of attachment that correspond to these behavioral changes, which are modified slightly from Bowlby's (1982) original formulation, are described in Table 58.1.

From a clinical perspective, we emphasize that two conditions appear to be necessary for infants to form attachments to adult caregivers. First, infants must have a significant amount of interaction on a regular basis with the caregiver. Infants can neither develop nor sustain attachments to adults with whom they have contact for only a few hours a week, although they may have positive social and playmate relationships with considerably less contact time. Second, they must attain a cognitive age of 7–9 months before the kind of preference seeking that defines attachment is present.

By the end of the first year of life, it is possible to assess the quality of the young child's attachment to a particular caregiver. Usually, this is accomplished by means of a laboratory paradigm known as the Strange Situation Procedure (Ainsworth *et al.*, 1978). Alternating episodes of separations and reunions between a young child and a familiar caregiver and an unfamiliar adult or stranger, the procedure yields classification of a young child's pattern of attachment to the caregiver with whom he or she is assessed as secure, insecure/avoidant, insecure/resistant, or disorganized. It is important to note that these classifications are not diagnoses and should be considered risk and protective factors that are probabilistically related to clinical disorders. Although secure attachment may confer protection for young children in high-risk environments (McGoron *et al.*, 2012), major risks for psychopathology appear to be associated with disorganized or other aberrant attachments (Green & Goldwyn, 2002; Zeanah *et al.*, 2011).

Table 58.1 Development of attachment in early childhood.

Age	Phase	Characteristics
Newborn—2 months	Limited discrimination	Ability to discriminate among different caregivers is limited and preferences are not readily observable
2–8 months	Discrimination with limited preference	Clearly discriminates different caregivers as evident by different patterns of interacting but usually engages readily with strangers and familiar caregivers
8–12 months	Focused attachment	Begins when separation protest and stranger wariness appear. Infant becomes notably more wary of interacting with strangers and protests readily if he or she anticipates or experiences separation from a preferred caregiver (i.e., attachment figure). In typical rearing circumstances, infants attach to more than one caregiver and demonstrate a hierarchy of preferences evident when stressed, fatigued or frightened
12–20 months	Secure base	Independent ambulation ushers in increasing exploratory forays away from the attachment figure, alternating with returns in which proximity is sought. Different patterns of attachment reflect differences in balance between exploration and secure base behavior
20 months and beyond	Goal corrected partnership	Attachment relationship shifts from nearly complete dependency on the caregiver to one in which the toddler becomes aware that others, including the caregiver, have intentions and wishes different from their own

Attachment classifications and psychopathology

Infant behaviors in the presence of the parent or caregiver suggesting fearfulness, freezing, or other contradictory attachment behaviors (e.g., initial approach followed by avoidance while in close contact with the caregiver) during the Strange Situation Procedure are indices of a disorganized attachment classification. Although disorganized attachment has a prevalence of 14% in low-risk samples (van IJzendoorn *et al.*, 1999), it is as high as 75–80% in maltreated and institutionalized samples (Carlson *et al.*, 1989; Vorria *et al.*, 2003; Zeanah *et al.*, 2005). Furthermore, disorganized attachment is associated with various disturbances in caregiving behavior, including frightening/frightened behavior, as well as antagonism, role confusion, withdrawal, and contradictory cues (Lyons-Ruth *et al.*, 1999; Schuengel *et al.*, 1999). As some children reach preschool age, disorganization is transformed into controlling/punitive or solicitous/caregiving behaviors directed toward the parent, though in some high-risk preschool samples, disorganized behaviors remain evident (Smyke *et al.*, 2010).

Of the various attachment classifications, disorganized attachment has the strongest links to subsequent psychopathology, including social difficulties, role-inappropriate parent–child

interactive behavior, peer rejection and poor social adjustment, aggression, and disruptive behavior in middle childhood, in addition to emotional problems, low self-esteem, and dissociative disorders in adolescence (Green & Goldwyn, 2002).

Most descriptions of attachment as a clinical disorder have derived from studies of the effects on social and emotional development in young children who have experienced severe deprivation, such as that associated with institutional rearing. Because of that, we turn next to a brief review of the association between institutional care and attachment disorders and consider how studies of institutionalized children informed psychiatric nosologies.

Historical considerations

Institutional care and deprivation

Maternal deprivation and the material deprivation that often accompanies it have long been recognized as important risk factors to development in humans (Chapin, 1915; Spitz, 1945; Bowlby, 1965; Rutter, 1981), primates (Suomi *et al.*, 1976; O'Connor & Cameron, 2006) and rodents (Zhang *et al.*, 2002; Hofer, 2006). For the past 50 years, children raised in institutions have been studied to assess the risks associated with this atypical rearing environment because it has been associated with deprivation. A series of small-scale descriptive studies began to raise questions about the consequences of institutionalization in the 1940s. Early studies focused on behavioral and cognitive manifestations of the effects of poor rearing environments (Goldfarb, 1945; Levy, 1947). In addition to disturbances of growth, cognitive development, and language, these studies also documented that children who had been institutionalized during the first 3 years of life demonstrated consistently greater levels of problem behaviors, including feeding and sleeping difficulties, aggressive behavior and hyperactivity, and excessive attention-seeking and sociability with strangers when compared with children in foster care.

A recent resurgence in studies of children adopted or fostered out of Romanian and other institutions has demonstrated some significant problems across a range of outcomes, including disturbed attachment (Chisholm, 1998; Vorria *et al.*, 2003; The St. Petersburg—USA Orphanage Research Team, 2008; Dobrova-Krol *et al.*, 2010; Rutter *et al.*, 2010; Bakermans-Kranenburg *et al.*, 2011; Smyke *et al.*, 2012). These findings have elaborated many important features of the disorders which had been defined descriptively by previous studies of children living in conditions of deprivation.

Tizard's study

Barbara Tizard's (1977) landmark study deconstructed the institutional experience by largely removing the material deprivation often associated with institutional care and focusing selectively on the variable of caregiver—child relationship. She described the cognitive and socioemotional development of a group of

children who experienced varying lengths of institutional care in residential nurseries in Great Britain in the early 1970s. Caregiver to child ratios in these nurseries were substantially better than those found in older studies of institutions (Goldfarb, 1945; Provence & Lipton, 1962). Children were maintained in small, mixed age groups, in a stimulating environment which included books, toys, and instruction (Tizard, 1977).

Three groups of children with histories of early institutional rearing were studied at age 4 years: 24 children who were adopted between 2 and 4 years of age, 15 children who were returned to their biological families (often despite marked ambivalence on the part of their parents), and 26 children who remained institutionalized between 2 and 4 years of age (Tizard, 1977). By age 4, this latter group had experienced an average of 50 different caregivers who had cared for the child for at least a week. Of these 26 children who remained in the residential nurseries, 8 had developed a preferred attachment, 8 were withdrawn and unresponsive, and 10 were indiscriminate, attention-seeking, and socially superficial (Tizard & Rees, 1975). The latter two groups displayed behaviors that had been described in some earlier studies and formed the basis of RAD and disinhibited attachment (DA) disorder in ICD-10 (World Health Organization, 1992).

An important contribution of this landmark study is that much of the material and even social privation that is evident in studies of children in other institutional settings (such as the contemporary studies of children raised in Romanian, Ukrainian, or Russian institutions) were not present. Because these residential nurseries were better staffed, had smaller groups of children, and included adequate material resources, this study permitted isolating the effects of the variable of interest for attachment disorders, that is, children's opportunity to form selective attachments to caregivers. Because caregivers were explicitly discouraged from forming attachments to children (or encouraging children to attach to them), the Tizard study showed that this particular caregiving condition was linked clearly to the phenotypes that we now call attachment disorders.

Attachment disorders in nosologies

RAD of Infancy first appeared in the DSM-III (American Psychiatric Association, 1980). Disordered social and emotional development was a hallmark of the disorder, which also included failure to thrive. Inexplicably, there also was a requirement that the disorder be manifest prior to 8 months of age; that is, prior to the age at which preferred attachment ordinarily emerges (Zeanah, 1996).

Subsequent versions of the DSM removed this requirement and made the age of onset below 5 years of age. However, in DSM-IV (American Psychiatric Association, 1994), a specified etiology was included: the child's signs of disturbed attachment were in response to "pathogenic care." ICD-10 (World Health Organization, 1992) criteria were generally consistent with DSM criteria. ICD-10 criteria do not specify pathogenic care,

but they do caution against making the diagnosis in the absence of a history of maltreatment.

Interestingly, all revisions in criteria in nosologies through DSM-IV (American Psychiatric Association, 1994) and ICD-10 (World Health Organization, 1992) occurred in the absence of systematic research of the disorders. Two other sets of criteria for disorders of attachment have been published since 2000, the Research Diagnostic Criteria-Preschool Age (RDC-PA; AACAP Task Force on Research Diagnostic Criteria: Infancy and Preschool Age, 2003) and the Diagnostic Classification: 0-3R (Zero to Three, 2005). These descriptions differed from DSM-IV-TR (American Psychiatric Association, 2000) and ICD-10 by focusing more explicitly on disturbed attachment behaviors rather than disturbed social behaviors more generally. The DSM-5 criteria (American Psychiatric Association, 2013) including defining two distinct disorders were based primarily on research in the last decade. Chapter 7 discusses more generally how classifications of early childhood disorders are made in different nosologies.

Clinical disorders of attachment: the phenotypes

Attachment disorders, which have been assessed both continuously and categorically, describe a constellation of aberrant attachment behaviors and other social behavioral anomalies in early childhood which are believed to result from the child having limited opportunities to form selected attachments. Historically, attachment disorders have been linked to deprivation or social neglect. The diagnosis is excluded in the presence of autistic spectrum disorders to distinguish them from social abnormalities associated with those disorders. Although attachment classifications are relationship-specific for the young child, signs of attachment disorders must be evident across situations and relationships.

Two clinical patterns of attachment disorders have been described:

- 1 An emotionally withdrawn/inhibited pattern, in which the child exhibits limited or absent seeking or responding to comfort when distressed, and a variety of aberrant social and emotional behaviors, such as lack of responsiveness and reciprocity, reduced positive affect, and emotion regulation difficulties. In both ICD-10 and DSM-5, this is called RAD. Evidence suggests that this disorder represents absence of preferred attachment in children who are old enough to have formed them. In keeping with this formulation, institutionalized children showed moderately high convergence between observer rated absence of attachment behaviors with familiar caregivers and caregiver reports of RAD (Zeanah *et al.*, 2005).
- 2 An indiscriminately social/disinhibited pattern, in which the child exhibits lack of expectable selectivity in seeking comfort, support, and nurturance, with lack of social reticence with unfamiliar adults, including a willingness to “go

off” with strangers and a violation of expected verbal and social boundaries with relative strangers. In ICD-10 (World Health Organization, 1992), this is called disinhibited attachment disorder (DAD) and in DSM-5 (American Psychiatric Association, 2013), this is called DSED. The essence of this disorder is indiscriminate social behavior in children who are expected developmentally to show some degree of stranger wariness.

Reactive attachment disorder

Core features of RAD include lack of social and emotional responses, an absence or near-absence of attachment behaviors even in times of stress, and serious problems of emotion regulation. In addition, RAD includes a paucity of positive emotional responses and bouts of fear or irritability that are seemingly unprovoked, or at least out of proportion to the situation. Social and emotional reciprocal interactions are absent or at least severely dampened. Cognitive and language delays, though not core features, are often associated with RAD because the conditions of neglect believed to lead to this pattern of attachment disorder are also associated with developmental delays.

These signs have been described in young children with a history of severe maltreatment (Zeanah *et al.*, 2004) and those being raised in institutions (Smyke *et al.*, 2002; Zeanah *et al.*, 2005). Interestingly, they have been much less noted in children adopted out of institutions (Chisholm, 1998; Rutter *et al.*, 2010).

Disinhibited social engagement disorder/disinhibited attachment disorder

Core behavioral features of this disorder in young children include inappropriate approach to unfamiliar adults, a lack of wariness of strangers, failure to check back with a caregiver in unfamiliar settings, and a readiness to accompany a stranger, and wander away from a familiar caregiver. Indiscriminate behavior also may be associated with lack of appropriate verbal and physical boundaries, so that children may interact with strangers intrusively and aggressively and may even seek out physical contact (O'Connor & Zeanah, 2003).

For example, some investigators have referred to “indiscriminately friendly” behavior (Chisholm, 1998; Tarullo *et al.*, 2011), but others have suggested that these terms imply more than is actually known about the nature of the child’s behavior (O'Connor & Zeanah, 2003). Some children exhibit passive lack of reticence and willingness to accompany a stranger, but this may be quite distinct from children who eagerly accompany a stranger without even checking back with their putative attachment figure. Other behaviors subsumed under this description include lack of initial reticence around unfamiliar adults (e.g., sitting in the lap of an unfamiliar adult at an initial meeting), actively choosing to approach an unfamiliar adult over an attachment figure in times of need, failing to monitor the whereabouts of the attachment figure in unfamiliar settings, displaying inappropriate social boundaries (e.g., making eye contact for too long or asking overly personal questions on initial meeting), or verbally or physically aggressive engagement

of unfamiliar adults. These behaviors are not experienced as sociable or friendly by those on the receiving end, and they are not always indiscriminately demonstrated (O'Connor & Zeanah, 2003). Because of this heterogeneity, more precise delineation of behaviors subsumed by this term is indicated.

Still, measurement of the construct has been reasonably consistent across studies. For example, comparing three different caregiver interview measures of indiscriminate behavior, Zeanah and colleagues (2002) showed substantial convergence across measures. Subsequent studies have shown concordance between interviews and observational measures (O'Connor *et al.*, 2003; Gleason *et al.*, 2011a; Oliveira *et al.*, 2012).

Middle childhood and adolescence

Less is known about the measurement of attachment in middle childhood than early childhood. There is no gold standard comparable to the Strange Situation Procedure, and the observable behaviors used to index attachment are less apparent in middle childhood. Not surprisingly, this means defining disordered attachment in this age group is challenging.

Minnis and colleagues have conducted a series of studies relying on combinations of parent report, standardized observations, and structured psychiatric interviews identifying RAD in school-aged children (Millward *et al.*, 2006; Minnis *et al.*, 2006; Minnis *et al.*, 2007; Minnis *et al.*, 2009). Nevertheless, their measures of RAD differ in important ways from the way RAD is defined in early childhood. There was no requirement for "pathogenic care" and an amalgam of disinhibited/indiscriminate behaviors and inhibited/emotionally withdrawn behaviors were included. Therefore, it is likely that the phenotype being described is not the same as the one described in early childhood, since they differ in important respects.

Indiscriminate behavior, on the other hand, has been described and studied in several different populations of children longitudinally from early to middle childhood and has been defined reasonably similarly across studies (Tizard & Hodges, 1978; Bruce *et al.*, 2009; Smyke *et al.*, 2012).

The most careful and intentional examination of the DSED phenotype in middle childhood to date was the English and Romanian Adoptees Study (Rutter *et al.*, 2007a, b). They used a combination of an examiner-based interview of parents when children were 6 and 11 years old and observed interactions with an unfamiliar adult. A factor analysis suggested that two internally consistent composites best summarized the data: violation of boundaries and physical contact. They found significant convergence in these measures of indiscriminate behavior, suggesting a cohesive construct across middle childhood.

In adolescence, Hodges and Tizard (1989) reported no relationship between indiscriminate behavior with unfamiliar adults at age 8 and age 16 years. However, they did report that children who had shown indiscriminate behavior at age 8, tended to be indiscriminate with peers at age 16. Rutter and colleagues (Kreppner *et al.*, 2010) reported the persistence of DA into

adolescence as part of their examination of deprivation-specific psychological (DSP) patterns. They noted the changing clinical picture as they tracked DA from early childhood, where specific behavioral patterns were more defined, to adolescence. They developed measures to assess DA in a way which reflected issues associated with the emerging developmental tasks of adolescence, including difficulties with social boundaries and behaviors which appeared flirtatious to others but were not thought to be so by the previously institutionalized young person. On the other hand, they noted that at times the intrusive and outgoing social style exhibited by some of their subjects had seemed to become a relative social strength in interaction with peers. Nonetheless, symptoms of DA appeared to persist in close to 70% of children who had exhibited DA signs earlier on (Kreppner *et al.*, 2010).

Differential diagnosis

RAD shares some features with autistic spectrum disorders, including disturbances in emotion regulation and impaired or absent social and emotional reciprocity. In addition, children with either disorder may have cognitive delays or stereotypies. However, children with RAD should not have a selective impairment in pretend play, repetitive preoccupations, or language abnormalities other than delays. Further, they should have a history of seriously adverse caregiving. Because RAD and cognitive delays are associated with severe deprivation, meaning social neglect warranting intervention by child protection or institutional rearing (Zeanah *et al.*, 2006), RAD also may be confused with intellectual disability. Young children with RAD should be distinguishable from children with intellectual disability because the latter group has social and emotional behaviors that are consistent with their developmental age, whereas children with RAD show clear evidence of deviance in their social responsiveness and regulation of emotion. Clearly, both conditions may co-occur.

DSED may share features of attention deficit/hyperactivity disorder, particularly impulsivity. Both ADHD and DSED have been reported as sequelae of institutional rearing, and they have both been defined as deprivation specific behavior patterns in postinstitutional children (see Rutter *et al.*, 2010). Roy and colleagues (Roy *et al.*, 2004) found that school-age children with a history of institutional rearing had high levels of both DA behavior and inattention/hyperactivity, as well as a strong association between the two. In addition to lack of selectivity in relationships with caregivers, the children also showed lack of selectivity with peers, echoing the findings of Hodges and Tizard (1989) with adolescents who had formerly been indiscriminate with caregivers. Less clear has been whether the social impulsivity of DSED is related to the cognitive and behavioral impulsivity of ADHD. In children with histories of institutional or other challenging rearing environments, impulse control difficulties are apparent in some children who exhibit

indiscriminate behavior (Bruce *et al.*, 2009; Pears *et al.*, 2010), but it is clear that DSED and ADHD may be distinguished clinically (Gleason *et al.*, 2011a). A child with DSED without ADHD will not show inattention/distractibility or restless/overactive behavior in situations demanding quiet and focused behavior. In addition, there is no reason to expect impulsivity beyond social impulsivity in a child with DSED only. For children with ADHD who also demonstrate social impulsivity, both diagnoses may be appropriate if full criteria for DSED are evident. Willingness to accompany unfamiliar adults, on the other hand, is not a part of the ADHD phenotype, unless the child's attention is drawn to some specific activity (e.g., joining a game or throwing a ball).

Prevalence

There is a consensus that these disorders are rare, even though there have been no careful epidemiological studies of their prevalence in community samples. When diagnostic criteria are applied, both RAD and DSED are unusual in populations attending outpatient clinics and more likely to be detected in extreme populations, that is, in young children who have experienced severe deprivation (Chisholm, 1998; Smyke *et al.*, 2002; O'Connor *et al.*, 2003; Boris *et al.*, 2004; Zeanah *et al.*, 2004). In a sample of 300 children aged 2–5, recruited from pediatric clinics in Durham, North Carolina, Egger *et al.* (2006) found no cases of attachment disorders using DSM-IV or the RDC-PA criteria (Boris & Zeanah, 2005). In a similarly designed study in Bucharest, Romania, Gleason and colleagues (Gleason *et al.*, 2011b), also found no cases of RAD.

Several recent studies of clinic-referred and high-risk children have assessed signs of disordered attachment using structured interviews and observational assessments. These studies have found that, even among maltreated children, few met criteria for attachment disorders, with the exception of some maltreated children in foster care (Boris *et al.*, 2004; Zeanah *et al.*, 2004; Oosterman & Schuengel, 2007). In a sample of 12- to 30-month-old children living in institutions in Bucharest, Romania, 10% met criteria for RAD and 24% for DSED (Zeanah, 2006). Thus, although signs of the disorder may be common in extreme populations, a minority of children seem to reach the threshold of disorder.

Etiology

Together with posttraumatic stress disorder, RAD and DSED are among the few psychiatric disorders in which the etiology is specified as one of the diagnostic criteria. A requirement of DSM-5 is that the child has experienced extremes of insufficient caregiving, such as serious social neglect or deprivation (i.e., persistent lack of having basic emotional needs for comfort, stimulation, and affection met), repeated changes of primary caregivers that limit opportunities to form stable attachments, or rearing in institutions that limit opportunities to form selective

attachments. Although DSED has been described in children with parents who have psychiatric disorders (see Chapter 28), and many children in foster care have parents with these disorders or serious substance use disorders, we caution against using parent characteristics other than caregiving behavior to identify extremes of insufficient care. It is the seriously deficient caregiving and not the feature associated with it that should be identified. In ICD-10, clinicians are cautioned about making the diagnosis in the absence of a history of maltreatment.

In the Bucharest Early Intervention Project (BEIP), signs of RAD assessed by caregiver report and caregiving quality assessed by coding naturalistic interactions when children were living in institutions were compared. Quality of caregiving, defined by caregiver sensitivity, stimulation of development, positive regard toward child, absence of detachment, absence of flat affect, and absence of intrusiveness, was inversely related to signs of RAD (Zeanah *et al.*, 2005). This finding cannot address the direction of effects, but it does illustrate the grossly insufficient care associated with this disorder. For children in the same study with signs of DSED, no relationship with caregiving quality was found (Zeanah *et al.*, 2005).

Understanding the link with grossly insufficient care is especially important for indiscriminate behavior for at least three reasons. First, the boundaries between highly sociable children and children exhibiting pathologically indiscriminate behavior are not completely delineated. Second, some children with ADHD seem to be socially as well as cognitively and behaviorally impulsive, and this makes delimiting what is indiscriminate behavior challenging. Third, children with congenital abnormalities may exhibit high levels of indiscriminate behavior. Children with Williams syndrome, for example, have been reported to show high levels of indiscriminate behavior, even with more than adequate caregiving (Järvinen-Pasley *et al.*, 2010). Williams syndrome is caused by a microdeletion on chromosome 7q11.23, and is characterized by a tendency for affected individuals to approach persons they do not know and interact with them verbally. Parents of young children with Williams syndrome expend much effort to monitor their children's whereabouts and teach them to refrain from approaching strangers. Compared with nonaffected individuals, they are unable to distinguish threatening faces and consider them just as trustworthy as nonthreatening faces (Järvinen-Pasley *et al.*, 2010).

One study has explored vulnerability factors in children exposed to deprivation. In the BEIP, Drury and colleagues (Drury *et al.*, 2012) demonstrated that children with either the s/s genotype of a serotonin transporter gene variant (5HTTLPR) or BDNF val66met met allele carriers demonstrated the lowest levels of indiscriminate behavior in young children in foster care, but the highest levels in the care as usual (CAU) group who experienced more prolonged institutional rearing. Children with both “plasticity genotypes” had the most signs of indiscriminate behavior at 54 months if they were randomized to CAU, while those with both plasticity genotypes randomized to the foster care intervention had the fewest signs at 54 months.

These specific results need to be replicated before they are accepted, but they demonstrate an approach to delineating individual differences in vulnerability to environmental risk.

Course of the disorders

Based upon the results from several longitudinal studies, however, it seems clear that RAD and DSED generally have different courses.

Studies of children adopted out of institutions have not reported evidence of RAD following adoption (Tizard & Hodges, 1978; Chisholm, 1998; O'Connor *et al.*, 2003). Furthermore, in the BEIP, the first randomized controlled trial to evaluate an intervention for attachment disorders, children who were being raised in institutions were assessed between 11 and 30 months of age for signs of RAD. Half were randomized to a foster care intervention and half to CAU (continued institutional rearing). Follow-ups were conducted at 30, 42, 54, and 96 months of age. Signs of RAD in the group removed from institutions and placed in foster care dropped to the level of never institutionalized children by 30 months and remained low at every subsequent assessment age (Smyke *et al.*, 2012). For children in the CAU group, signs of the disorder slowly decreased over time, but they were always significantly greater than the intervention group. Further, the slow decline of signs of the disorder were accounted for completely by children who were placed in families—either reintegrated with their own biological families or placed into government sponsored foster care (Smyke *et al.*, 2012). In other words, over a 6-year period, there was no significant reduction in signs of RAD for children who remained in institutions. This latter finding is important, as it represents preliminary evidence of persistence of the disorder in children who remain in an adverse caregiving environment. These results indicate that signs of RAD are eliminated by placement of children into families where they receive at least adequate care. Less clear is what the long-term sequelae of RAD in early childhood may be in adolescence or adulthood.

In contrast, there is reasonably clear evidence demonstrating that indiscriminate behavior persists over time—sometimes even after improvements in the caregiving environment. This was demonstrated originally in the work of Tizard and colleagues, who showed that young children who had been indiscriminate with caregivers at age 4 were more likely to have serious peer disturbances at 16 years, including superficial and even indiscriminate behavior with peers (Hodges & Tizard, 1989). Subsequent studies of children adopted into Canada and the UK from Romanian institutions have also demonstrated a tendency for indiscriminate behavior to persist even after the child forms attachments to the adopted family (Chisholm, 1998; O'Connor *et al.*, 2003). In fact, of those children adopted into the UK from Romanian institutions who had high levels of indiscriminate behavior at age 6, more than half continued to show high levels at age 11 (Rutter *et al.*, 2007a). Furthermore,

in the BEIP, indiscriminate behavior persisted in children who had been reared in institutions (Smyke *et al.*, 2012).

Clinical assessment

In keeping with recent trends in the assessment of early childhood psychopathology (delCarmen-Wiggins & Carter, 2004), attachment disorders are best identified through a combination of caregiver interview and observed interactions. In our view, there are no gold standard interviews nor observational paradigms of interactions between parents and children that must be included, but several useful approaches have been described.

Interviews

Structured interviews specifically focused on the child's attachment behaviors and signs of disordered attachment (O'Connor *et al.*, 1999; Smyke *et al.*, 2002; Boris *et al.*, 2004; Zeanah *et al.*, 2005) are more likely to be useful than interviews that are less specifically focused. At least two structured psychiatric interviews, the Psychiatric Assessment Preschool Age (Egger & Angold, 2004) and the Diagnostic Infant/Preschool Assessment (Scheeringa & Haslett, 2010) include modules on attachment disorders. These approaches are able to characterize attachment disorders both categorically and continuously.

Observations

Potentially clinically useful observations of parent and child together include procedures designed specifically to examine attachment behaviors (O'Connor *et al.*, 2003; Boris *et al.*, 2004; Oliveira *et al.*, 2012), or those in which other aspects of parent-child interaction are also assessed (Zeanah *et al.*, 2000). It is generally useful to include in the observation some degree of distress that is likely to activate the child's need for the attachment figure. Conventionally, this has involved brief separations followed by reunions, but other approaches such as a novel (i.e., scary) toy also have been used (Boris *et al.*, 2004). Although the Strange Situation Procedure was not designed for clinical assessments, in some circumstances it may be helpful (Zeanah *et al.*, 2011). The Circle of Security Intervention, for example, includes review of videotaped recordings of a child's Strange Situation behavior with the parent as a part of the intervention (Hoffman *et al.*, 2006). Although systematic observations of the child's behavior in paradigms designed to elicit attachment behaviors are often clinically valuable, naturalistic observations of a child's attachment behaviors also may yield important data.

Interventions

Studies of interventions for RAD and DSED are limited. Intervention efforts to date have been guided by the principle that enhancing the caregiving environment will ameliorate signs of

attachment disorder. Smyke *et al.* (2002), for example, studied signs of RAD and DSED in young children being raised in a large institution for young children in Bucharest. This institution had implemented a pilot unit designed to reduce the number of caregivers responsible for each child. In fact, compared to the more standard units, which included large numbers of rotating caregivers, on the pilot unit no more than four caregivers were responsible for each child on the day and evening shifts. Caregivers on the pilot unit reported that children had significantly fewer signs of both RAD and DSED. Importantly, this reduction was evident even though the ratio of caregivers to children remained at 1:12 on the pilot unit (the same as on the standard units).

Studies of young children adopted out of institutions are also useful to examine because they represent such a dramatic change in caregiving environments. Two longitudinal studies of young children adopted out of Romanian institutions are particularly instructive. A longitudinal study of young children adopted into Canada from Romanian institutions used parent reports of attachment and indiscriminate behavior. They found significant increases in attachment to adoptive parents during the first several years following adoption, although indiscriminate behavior persisted in a minority of children (Chisholm, 1998). Another longitudinal study of children adopted from Romanian institutions into families in the UK assessed signs of disordered attachment from parent reports at ages 4, 6, 11, and 15 (O'Connor & Rutter, 2000; O'Connor *et al.*, 2003; Rutter *et al.*, 2007a; Rutter *et al.*, 2010). They reported little change in the numbers of children with high levels of indiscriminate behaviors between 4 and 6 years, but some decline by age 11 years (O'Connor & Rutter, 2000; Rutter *et al.*, 2007a). To date, however, there has been no demonstration that quality of care in adoptive homes is inversely related to signs of indiscriminate behavior in children.

In summary, findings from studies of children living in institutions and those adopted out of institutions suggest that signs of DSED are remediated by enhanced caregiving only in some children. It is unclear whether this represents individual differences among children or partial remediation with persistence in those most severely affected initially. To date, adoption studies have not included assessments of children in the institutions prior to adoption, making it difficult to explain individual differences in response.

The only contemporary intervention study that included assessments of children's attachment prior to removal from institutions and placement in an enhanced caregiving environment is the BEIP, described earlier. Results of this study indicate that foster care leads to significant reductions in signs of RAD in young children who had signs of the disorder when they were living in institutions (Smyke *et al.*, 2012).

At this stage, clinicians must be guided by data indicating that secure attachment is fostered by caregivers who are emotionally available and sensitively responsive, who know and value the child as an individual, and who place the needs of the child ahead

of their own needs. Preliminary data indicate that psychoeducational approaches involving training parents to respond sensitively to their child (Juffer *et al.*, 2005) and to understand their own and their child's attachment pattern (Hoffman *et al.*, 2006) have been shown to promote attachment security in the child. These interventions are reasonable starting points for developing an evidence base about intervening in disordered attachments.

Conclusions

Our understanding of attachment disorders has deepened considerably in the past decade as a result of a number of systematic studies of children with histories of severe neglect or institutional rearing. These studies have affirmed the reliable identification of both RAD and DSED. They also have supported the link between extremes of inadequate caregiving and these disorders. Further, they have demonstrated that the specific "pathogen" is any environment in which young children have limited opportunities to form selective attachments, as happens in cases of severe social neglect or in settings in which the child lacks regular and consistent contact with an emotionally involved caregiver (e.g., institutional settings or frequent changes in foster care).

Although RAD and DSED arise from similar conditions of risk, they have different correlates and different courses. In particular, placement in enhanced caregiving environments seems to lead to rapid and complete elimination of signs of RAD, but DSED remains persistent in some children, apparently for years.

However, a number of questions remain to be addressed. First, not enough is known about individual vulnerabilities to the disorder—in particular, why such phenomenologically distinct syndromes arise from similar conditions of risk. Genetic polymorphisms, temperamental dispositions, and differential caregiving experiences should all be examined. In addition, the relationship between the two types of disorder—if any—needs to be clarified. Second, why some children with indiscriminately social/DA disorder seem to respond to enhanced caregiving and others do not is unclear. Third, the specific components of enhanced caregiving that are crucial for amelioration of signs of the disorder are unclear. This is especially important, given the heterogeneity of outcomes in postadoption studies. Fourth, the putative social cognitive abnormalities that characterize indiscriminate behavior need to be delineated. It seems reasonable that such abnormalities are the most concerning aspect of the disorder from the standpoint of functional impairment. Finally, the underlying neurobiology of these disorders is largely unexplored. The phenomenological similarities and differences between indiscriminate behavior and Williams syndrome may suggest hypotheses about the neural substrate of DSED. Answers to these questions will assist clinicians concerned with helping children recover from the long-term effects of early adversity.

CHAPTER 59

Post traumatic stress disorder

William Yule and Patrick Smith

Institute of Psychiatry, Psychology and Neuroscience, Kings's College London, UK

Characteristics and diagnosis of the condition

The diagnosis of posttraumatic stress disorder (PTSD) was first conceptualized in response to observations of Vietnam war veterans presenting with what came to be recognized as a particular pattern of symptoms in three clusters—intrusive recollections of a traumatic event; emotional numbing and avoidance of reminders of that event; and physiological hyperarousal. In retrospect, similar patterns were noted as reactions in earlier wars, and in prospect, the criteria were adapted, partly operationalized and applied to adult civilians. Next, the diagnosis was applied to children who had experienced an “event outside the range of usual human experience ... that would be markedly distressing to almost anyone” (American Psychiatric Association, 1987).

Thus, it was argued that there were certain types of stressful experiences that were very severe and/or unusual and that there was a distinctive form of stress reaction to these. PTSD was classified as an anxiety disorder, but many argued that it should be included as a dissociative disorder, and more recently it has been recognized as a disorder of memory. It was increasingly described as “a normal reaction to an abnormal situation,” and so, logically, it was queried whether it should be regarded as a psychiatric disorder at all (O'Donohue & Eliot, 1992). Far from being “abnormal,” exposure to traumatic events is all too common in childhood and adolescence (Giaconia *et al.*, 1995; Costello *et al.*, 2002). PTSD usually occurs in only a minority of those exposed to trauma (Copeland *et al.*, 2007). Comorbidity with other disorders is the norm rather than the exception (Bolton *et al.*, 2000). Even if it were regarded as a normal reaction, it causes substantial impairment in sufficient cases to be regarded as a disorder.

While adult studies suggest that PTSD is predominantly an anxiety disorder, it differs from other anxiety disorders in

important ways. Thus, Foa *et al.* (1989) showed that the trauma suffered violated more of the patients' safety assumptions than did events giving rise to other forms of anxiety. There was a much greater generalization of fear responses in the PTSD groups, and, unlike other anxious patients, they reported far more frequent reexperiencing of the traumatic event. Indeed, it is this internal, subjective experience that seems most to mark out PTSD from other disorders (Jones & Barlow, 1992). Given that exposure to traumatic events is common (Kessler *et al.*, 1995), and that only a minority of exposed individuals go on to develop the disorder (e.g. McFarlane, 2005), the argument is therefore made that PTSD is an “abnormal reaction” that involves a complex interaction of biological, psychological, and social causes (Yehuda & McFarlane, 1995): exposure to trauma is insufficient to explain the development of the disorder. Current biopsychosocial and cognitive models (see later) are paying increasing attention to factors underlying individual differences in response to traumatic events. Concern has been expressed that there are other forms of stress reactions to chronic stressors as experienced in repeated physical or sexual abuse (see Chapters 27–30). While these are important debates that will alter the views taken on PTSD, here we will concentrate on acute conditions as manifested in children and adolescents.

Manifestations of stress reactions in children and adolescents

Immediately following a very frightening experience, children are likely to be very distressed, tearful, frightened, and in shock. They need protection and safety. They need to be reunited with their families wherever possible. Clinical experience, surveys, and clinical descriptive studies quoted below show that the main manifestations of stress reactions are as follows.

Starting almost immediately, most children are troubled by *repetitive, intrusive thoughts* about the accident. Such thoughts can occur at any time, but particularly when the children are otherwise quiet, as when they are trying to drop off to sleep. At other times, the thoughts and vivid recollections are triggered off by reminders in their environment. Vivid, dissociative *flashbacks* are uncommon. In a flashback, the child reports that he or she is reexperiencing the event, as if it were happening all over again. It is almost a dissociated experience. *Sleep disturbances* are very common, particularly in the first few weeks. Fears of the dark and bad dreams, nightmares, and waking through the night are widespread (and often manifest outside the developmental age range in which they normally occur).

Separation difficulties are frequent, even among teenagers. For the first few days, children may not want to let their parents out of their sight, even reverting to sleeping in the parental bed. Many children become much more *irritable and angry* than previously, both with parents and peers.

Although child survivors experience a pressure to talk about their experiences, paradoxically they also find it very *difficult to talk* with their parents and peers. Often they do not want to upset the adults, and so parents may not be aware of the full extent of their children's suffering. Peers may hold back from asking what happened in case they upset the child further; the survivor often feels this as a rejection.

Children report a number of cognitive changes. Many experience difficulties in *concentration*, especially in school work. Others report *memory* problems, both in mastering new material and in remembering old skills such as reading music. They become very *alert to danger* in their environment, being adversely affected by reports of other disasters.

Survivors have learned that life is very fragile. This can lead to a loss of faith in the future or a sense of foreshortened future, or a premature awareness of their own mortality. Their priorities change. Some feel they should live each day to the full and not plan far ahead. Others realize they have been overconcerned with materialistic or petty matters and resolve to rethink their values. Their "assumptive world" has been challenged (Janoff-Bulman, 1985).

Not surprisingly, many develop *fears* associated with specific aspects of their experiences. They avoid situations they associate with the disaster. Many experience "survivor guilt"—about surviving when others died; about thinking they should have done more to help others; about what they themselves did to survive.

Adolescent survivors report significantly high rates of *depression*, some becoming clinically depressed, having suicidal thoughts and taking overdoses in the year after a disaster. A significant number become very *anxious* after accidents, although the appearance of panic attacks is sometimes considerably delayed. Some children may have been bereaved and may develop *traumatic grief* reactions.

In summary, children and adolescents surviving a traumatic event may show a wide range of symptoms which tend to cluster around signs of reexperiencing the traumatic event, trying to

avoid dealing with the emotions that this gives rise to, and a range of signs of increased physiological arousal. In a substantial minority, this cluster of symptoms will amount to a diagnosable PTSD. Just as in adults, a broad range of adverse outcomes is common (Bolton *et al.*, 2000; Pine & Cohen, 2002): there may be considerable overlap of symptoms with depression, generalized anxiety, or pathological grief reactions although whether this indicates the presence of mixed disorders or comorbidity of separate disorders remains to be clarified.

However, this has implications for assessment. It is not sufficient to enquire solely about symptoms of PTSD. Symptoms of anxiety, depression, and grief need also to be formally investigated. Nor are self-completed questionnaires measuring these aspects sufficient to make a diagnosis. They have an important role, but sensitive clinical interviews with the child and separately with the parents remain the cornerstone of good assessment.

Developmental aspects

Considerable debate remains as to whether the very young child's limited cognitive development is protective against developing a chronic posttraumatic stress reaction. Certainly, until recently, the diagnostic criteria in both of the major classification schemes were not appropriate for preschool children.

Some community surveys of trauma-exposed children reported very low rates of PTSD diagnosis according to DSM-IV criteria. None of the very young children exposed to the September 11 attacks in New York and studied by Saigh *et al.* (2011) met criteria. Are the children very resilient or are the criteria developmentally insensitive?

In a series of studies, Scheeringa and colleagues (Scheeringa *et al.*, 1995, 2001, 2003, 2006) examined the phenomenology reported in published cases of trauma in infants and young children and evolved an alternative set of criteria for diagnosing PTSD in very young children. This alternative algorithm (PTSD-AA) reduces the threshold for diagnosis by dropping the required number of avoidance symptoms (the most difficult to elicit in young children) and reformulating other criteria in more developmentally appropriate terms.

The DSM-5 criteria for "PTSD-Preschool subtype" closely match the research criteria developed by Scheeringa. De Young *et al.* (2011) examined children aged 1–6 following burns and found that the PTSD-AA and DSM-5 identified nearly identical children. At 1 month post trauma, both methods diagnosed 25% as having PTSD, and this is considerably more than the incidence of 5% yielded by DSM-IV criteria.

Cultural issues

Traumatic events such as wars and natural disasters happen globally, but especially in low and middle income countries

where mental health services are often least developed. There is continuing debate about how best to meet mental health needs in differing cultures. The validity of Western frameworks for assessment and intervention needs to be constantly reviewed.

PTSD presents very similarly in many different cultures, but ways of intervening may need to be modified. For example, very similar stress reactions have been reported in children across all continents where studies have been undertaken (in Europe: Giannopoulou *et al.*, 2006; North America: Pynoos *et al.*, 2008; Central America: Arroyo, 1997; the Middle East: Thabet & Vostanis, 1999; Southeast Asia: Neuner *et al.*, 2006; Australasia: Bryant *et al.*, 2007; and elsewhere: Perrin *et al.*, 2000).

If PTSD “transcends cultural barriers” (Sack *et al.*, 1997), then similar underlying factor structures should be found if similar self-completed screening questionnaires are measuring the same construct (Smith *et al.*, 2003). To date, this has been the case in Cambodia (Sack *et al.*, 1997, 1998), Croatia (Dyregrov *et al.*, 1996) and Bosnia (Smith *et al.*, 2003). Large-scale studies in China have also replicated the same underlying factors (Ma *et al.*, 2011) indicating that stress reactions are indeed more similar than different across cultures.

It might be argued that the use of questionnaires constrains the way children can express their reactions. Open-ended interviewing and ethnographic methods, however, come to the same conclusion. Bolton (2001) found that the postgenocide symptoms reported by Rwandan youth were very close to those described in DSM-IV for both PTSD and depression.

Thus, the evidence at present is that posttraumatic stress reactions are not culture bound.

Impact of disorder on functioning

Given that PTSD affects mood, memory, and learning, it is surprising how few studies are reported on the effect of trauma on academic attainment. Tsui (1990; reported in Yule & Gold, 1993) found that adolescent girls who survived the sinking of the cruise ship “Jupiter” showed a marked decline in academic attainments a year later when compared with peers of matched ability who had not gone on the cruise. Broberg *et al.* (2005) found that 2 years after a devastating discotheque fire, adolescents reported significant effects on school attainment. Only 17% reported no impact on schooling while nearly a quarter had had to repeat a year or even dropped out of education. More generally, community violence was reported to have significant adverse effects on the educational attainment of adolescents. Those who developed severe PTSD scored significantly lower grade point averages than those with moderate PTSD. Fortunately, their attainment responded to treatment of their PTSD (Saltzman *et al.*, 2001). Dyregrov (2004) indicates how PTSD reactions can interfere with learning, self control and peer relationships within school and advises that schools be better prepared to help traumatized children.

Differential diagnosis

Differential diagnosis should not be difficult, provided clinicians take a good trauma history as part of their normal screening procedures (Greenwald, 2005). Without this, it could be possible to misidentify intrusive phenomena as hallucinations or delusions. Similarly, poor concentration and difficulty learning might be confused with Attention Deficit Hyperactivity Disorder (ADHD). In general, differential diagnosis is more complicated following multiple exposure but appears more straightforward following single-incident trauma.

Assessment

In contrast to other child mental health complaints, the traumatic event is likely to be well known (other than sexual or physical abuse). Therefore, when a referral is made, the clinician can gather together considerable detail of the incident in the form of press reports, photographs, videos, and even architectural drawings. This can greatly help the child recall details of the experience and places it in context.

The initial assessment should involve a brief joint parent and child meeting to describe the interview process. This is followed by asking parents and child separately to complete standardized, self-report measures, and then conduct separate parent and child interviews. Children will frequently reveal details of what happened and how they reacted during their interview, details of which the parents are unaware. Indeed, parents and children frequently avoid discussing the incident for fear of upsetting each other. This is why it is vital to get the child’s own account when the parent is not present. All clinicians and researchers need to have a good understanding of children’s development to be able to assist them express their inner distress.

A great deal can be achieved in this first session. The therapist aims to engage the child and parents in therapy as well as assess problems for planning treatment. All too often, children are referred long after the traumatic event and will have built-up patterns of avoiding discussing the trauma. The child often feels that the reactions are out of control and so the therapist must show that the child can get control over small aspects, such as deciding whether the child or parents are interviewed first. Every opportunity is taken even at this early stage to normalize the child’s reactions—not dismissing them, but getting across the message that they are frequent and well understood. The information is used to set treatment goals and the child and parents are given the rationale for trauma-focused cognitive behavioral therapy (CBT) which is outlined.

It is very rare to find a child presenting with only PTSD. Separation anxiety, depression, bereavement reactions, fears, and so on may be present. Thus, it is important that the early assessment enquires about this whole range of problems. To cut down on the time involved, the clinician can use a variety of self-completed questionnaires with children aged over 7 or 8 years of age, and parallel ones completed by their parents.

Effective social support is key to good prognosis. Mental health problems in parents can greatly interfere with the support they can give the child. This is especially true when parent and child have been in the same incident. Thus, a careful evaluation of the parents' adjustment is needed. Where the traumatic incident has involved personal violence, it is important to assess the extent of any ongoing risk to the child.

No specific physical investigations are necessary. Increasingly, there is evidence (reviewed later) that a number of peri- and posttraumatic factors influence the development and course of PTSD. It is already possible to measure children's cognitive distortions, and further diagnostic tools will become available in the near future. Thus, at an early stage of assessment it will be possible to identify key issues that will be targeted in therapy. In general, what is needed is for clinicians to obtain much better trauma histories and pay attention to the ways in which children react to the traumatic event (Greenwald, 2005).

Epidemiology

Estimates of the incidence of PTSD in trauma-exposed children vary enormously, partly as a result of differing methodologies, and partly as a result of different types of traumatic event. Studies of the mental health of child refugees from war torn countries find the incidence to be close to 67%. Sexual abuse results in high rates of PTSD (Salmon & Bryant, 2002), as does witnessing violence (Margolin & Gordis, 2000). In various studies of the effects of traffic accidents, rates of 15–30% are reported (e.g. Stallard *et al.*, 2004). A study of 200 adolescent survivors of the sinking of the cruise ship "Jupiter" (Yule *et al.*, 2000) reported an incidence of PTSD of 51%. Most cases manifested within the first few weeks with delayed onset being rare. Following a nightclub fire in Gothenburg, 25% of the 275 adolescent survivors met DSM-IV criteria for PTSD 18 months after the fire (Broberg *et al.*, 2005). This appears fairly constant across developmental levels. In other words, significantly increased demands will be made at all levels of primary and secondary child and adolescent mental health services following major traumatic events.

Most epidemiological studies have been of older adolescents and adults. For example, Giaconia *et al.* (1995) report a lifetime prevalence of 6% in a community sample of older adolescents. More recently, Merikangas *et al.* (2010) report a lifetime prevalence of 5% using data collected from adolescents (up to 18 years old) in the United States National Comorbidity Survey—Adolescent Supplement. A national sample of eighth grade Danish students estimated a 9% lifetime prevalence (Elklit, 2002). By contrast, the British National Survey of Mental health of over 10,000 children and adolescents (Meltzer *et al.*, 2003) report that only 0.4% of 11–15-year-olds were diagnosed with PTSD, with girls showing twice the rate of boys. Below age 10, it was scarcely registered. This lower rate is, of course, a point prevalence estimate and is bound to be lower than a lifetime prevalence estimate. Moreover, the screening instrument was

not specifically developed to screen for PTSD. The implication is that while the numbers of children and adolescents experiencing PTSD at any one point in time may be as low as 1%, this is still a significant level of morbidity in any community.

Most teachers will hardly ever encounter a child who suffers from it. When they do, they may be ill-prepared to deal with it. In addition, professionals in primary care frequently underestimate how often PTSD does occur in children (Ehlers *et al.*, 2009). However, it is important for all service providers and planners to remember the difference between incidence and prevalence. While the point prevalence and lifetime prevalence may appear low, the incidence following a particular disaster may overwhelm local services.

Large-scale disasters such as the attacks in New York on September 11, the London underground on July 7 and Hurricane Katrina result in many children being exposed directly and indirectly to the traumatic event. Such incidents require a different clinical response from the usual individual referral. Indeed, communities and schools should have emergency plans in place that allow quick response and appropriate care of those exposed. In turn, this argues for better screening of large numbers. Appropriate early screening does not mean that inappropriate early intervention is undertaken. Rather it permits a rational and efficient "screen and treat" approach to ensure that those most affected receive help (Brewin *et al.*, 2010a). As Mollica *et al.* (2004) argued, few communities have tried and trusted procedures in place to deal with the mental health consequences of complex emergencies. Agencies such as WHO and NCPTSD have suggested ways of responding, although these have not always been evidence-based.

Longitudinal outcome

Data from numerous adult studies show that there is substantial natural recovery from PTSD in the initial months after the trauma. Many individuals recover from PTSD without treatment, and the steepest decline in rates of PTSD is usually seen in the first year. This still leaves a substantial minority—roughly a third—who are likely to develop a chronic disorder which may persist for years if left untreated (National Institute for Health and Care Excellence (NICE), 2005).

A similar picture is emerging from prospective follow-up studies of children. For example, Meiser-Stedman *et al.* (2005) found that among young survivors of assaults and traffic accidents, nearly one in five met criteria for acute stress disorder (ASD) 2–4 weeks after the event. When reinterviewed at 6 months posttrauma, the rate of PTSD was 12%. The question remains: What factors distinguish those children who will recover spontaneously from those who will go on to develop a chronic reaction requiring treatment?

There have been very few long-term follow-up studies of children who developed PTSD. The 5–7-year follow-up study of adolescents who survived the sinking of the cruise ship "Jupiter"

found that 15% still met criteria for PTSD long after the event (Yule *et al.*, 2000).

A 33-year follow-up of the children who survived the Aberfan land-slide disaster found that 29% of those traced and interviewed still met criteria for PTSD (Morgan *et al.*, 2003). Exposure to trauma in childhood is also associated with a broad range of adverse psychiatric outcomes in adulthood. For example, in a large epidemiological study ($N=43,000$ adults), physical abuse in childhood was associated with increased lifetime prevalence of ADHD, PTSD, bipolar disorder, panic disorder, substance abuse, generalized anxiety, and major depression after the age of 18 (Sugaya *et al.*, 2012). Similarly, Copeland *et al.* (2013) found that young adults who had been victims of bullying in childhood were at increased risk of anxiety disorders, depression, and suicidality. Childhood trauma is also associated with psychotic symptoms in adulthood (e.g. Aas *et al.*, 2011; Aresenault *et al.*, 2011; Heins *et al.*, 2011) and with conduct problems (e.g. Jaffee *et al.*, 2005). The effects of life-threatening traumatic events in childhood can be severe and very long-lasting.

Risk factors

The established finding that only a minority of trauma-exposed young people will develop a persistent PTSD has led to the search for risk factors. Findings from such research have potential for practical clinical application. For example, identification of fixed markers (such as severity of trauma exposure, or gender) may be useful in identifying children most at risk so that services can be directed to them; identification of causal risk factors (such as cognitive misappraisals) may help to define targets for therapeutic intervention.

Early studies investigated whether the severity of exposure to trauma was associated with later pathology. There is now good evidence for a significant exposure–response relationship among children exposed to single-event trauma (e.g. Pynoos *et al.*, 1987), war (e.g. Gupta *et al.*, 1996; Smith *et al.*, 2002) and mass disaster (e.g. La Greca *et al.*, 2010). In a series of large-scale studies of children exposed to hurricanes, La Greca and colleagues (2010) have shown that this relationship is not straightforward: in addition to a direct link between exposure and PTSD, exposure also predisposes to further life events and disrupts social support, which in turn influence persistent PTS symptoms. A recent meta-analysis (of 96 studies; total $N=74,000$) of children exposed to disaster (Furr *et al.*, 2010) found a medium effect size ($r=0.33$) of exposure severity, measured by proximity to the event, on PTS symptoms. In sum, there is a significant relationship between the “objective” level of trauma exposure and later adjustment across a broad range of trauma types. However, the strength of this relationship is generally modest.

In this context, researchers have investigated additional factors that may be associated with the development of persistent PTSD. Trickey *et al.*’s (2012) meta-analysis of risk factors provides a

helpful and timely account of this rapidly growing area. Using data from $k=64$ studies (total $N=32,000$ children and adolescents aged 6–18 years) which included a broad range of trauma types, population effect size estimates were derived for 25 potential risk factors for PTSD. In line with two key meta-analyses of risk factors in adults (Brewin *et al.*, 2000b; Ozer *et al.*, 2003), it was found that peri- and posttraumatic factors showed larger effect sizes on persistent PTSD than pretrauma demographic factors and the severity of exposure. Specifically, fixed markers such as age, gender, and ethnicity showed negligible to small effects ($\rho=0.03$ – 0.15). Objective trauma severity showed a small to medium effect ($\rho=0.29$). Peri-traumatic variable risk factors such as fear and the perception of life threat during the event showed large effects ($\rho=0.36$). A number of posttrauma variable risk factors also yielded large effect sizes, including cognitive factors (thought suppression, blaming others, distraction; $\rho=0.47$ – 0.70); social and family factors (social withdrawal, poor family functioning; $\rho=0.38$ – 0.46) and psychological factors (severity of initial PTSD symptoms and comorbid psychological problems; $\rho=0.40$ – 0.64). Some caution is needed in interpreting these findings, given the relatively small number of included participants for some variables. However, in terms of clinical application, it is encouraging that the largest effects were found for variable risk factors that can in principle be targeted and modified in therapy.

For example, in line with clear predictions from cognitive models of the disorder (Ehlers and Clark, 2000), subjective appraisals appear to have a central role in maintaining PTSD in older children and adolescents. Both Furr *et al.*’s (2010) and Trickey *et al.*’s (2012) meta-analyses found perceived life threat to be at least as important as objective trauma severity in maintaining PTS symptoms. The role of subjective appraisal has been directly tested in a number of carefully designed prospective longitudinal follow-up studies of children exposed to single-event trauma such as assaults and accidents. Building on earlier work (Ehlers *et al.*, 2003; Bryant *et al.*, 2007; Meiser-Stedman *et al.*, 2007, 2009a, b; Salmon *et al.*, 2007), Nixon *et al.* (2010) recently found that the initial unhelpful appraisals of hospitalized injured children accounted for around 30% of the variance in PTS symptoms 6 months later. Misappraisals also appear important in the adjustment of children who have been repeatedly maltreated, abused or neglected (Leeson & Nixon, 2011). Cross-cultural evidence for the role of unhelpful trauma-related appraisals was also found in a very large study of the effects on children of the Wenchuan earthquake in China (Ma *et al.*, 2011). Finally, analog studies with adults using the trauma film paradigm have found that manipulating such appraisals using computerized training can ameliorate intrusive recollections (Woud *et al.*, 2012), implying that cognitive misappraisals are a causal risk factor. Indeed, an earlier randomized controlled trial (RCT) of trauma-focused cognitive behavioral therapy (TF-CBT) for young people with PTSD (Smith *et al.*, 2007) found that the effect of therapy was partially mediated by changes in unhelpful appraisals.

Family functioning and parental mental health posttrauma both show significant associations with children's PTS symptoms in a number of studies. At least 25 studies have established that poor parental mental health (depression, anxiety, and PTSD) correlates with child PTS symptoms, showing a medium effect size overall (Trickey *et al.*, 2012). In a prospective study of young attendees at an emergency department, Meiser-Stedman *et al.* (2006) found that parental depression was related to child PTS in the acute posttrauma period and 6 months later. Parental worry mediated the relationship between parental depression and child adjustment. Family functioning has been measured in various ways, for example using the Family Functioning Questionnaire, the Family Environment Scale, indices of Expressed Emotion, or *ad hoc* measures. Although there are far fewer studies of family functioning than parental mental health, initial effect size estimates are larger for family functioning than for parental mental health, and more research is needed. The mechanisms underlying these familial associations remain unclear. In part, they may derive from a complex interaction between parents and children who can become locked into cycles of not talking about the event for fear of upsetting each other. That is, carers and children may negatively reinforce each other for avoiding processing their traumatic memories, and this is likely to maintain the symptoms of both.

Social support may be highly relevant in the maintenance and resolution of PTSD (Pine & Cohen, 2002) but has been insufficiently studied in children. Trickey *et al.* (2012) estimated a medium effect size of social support on PTSD, but this was based on just four studies. La Greca *et al.* (2010) have shown in a large longitudinal study how social support may mediate the effect of trauma exposure on PTS symptoms among hurricane-exposed adolescents in the United States. McDermott *et al.* (2012) used a cross-sectional design to show that a related construct—social connectedness—was related to PTSD among children exposed to a cyclone in Australia.

Genetically informative studies of adults have established that PTSD risk is modestly heritable, but such findings have yet to be reliably replicated in children and adolescents. First, adult twin studies find evidence for some degree of heritability of risk for exposure to trauma, probably via genetic effects on personality (Stein *et al.*, 2002). Second twin studies of adults report heritability estimates of PTSD to be around 30% for males (True *et al.*, 1993), with higher estimates for females (Sartor *et al.*, 2011), and a striking degree of overlap in heritability of PTSD and depression in trauma-exposed adults (Sartor *et al.*, 2012). Third, molecular genetic studies have focused on candidate genes implicated in the dopaminergic, serotonergic, and noradrenergic systems, as well as on markers of the hypothalamic–pituitary–adrenal (HPA) axis (see Koenen *et al.* (2009) for a review). For example, a higher incidence of the short allele in the promoter region (5-HTTLPR) of the serotonin transporter gene (SLC6A4) was found in adults with PTSD compared to controls (Lee *et al.*, 2005). The same variant has been found to increase risk for PTSD when social support is

low (Kilpatrick *et al.*, 2007) and is associated with poorer treatment response to trauma-focused CBT (Bryant *et al.*, 2010). Further research with children and adolescents is needed.

Pathological risk processes

Physiological processes

Trauma exposure activates a neurobiological stress response in humans. It is proposed that traumatic stress activates the locus ceruleus and the sympathetic nervous system (SNS), resulting in increased heart rate, blood pressure, metabolic rate, alertness, and circulating catecholamines (adrenaline, noradrenaline, and dopamine). The locus ceruleus also stimulates the HPA axis, resulting in release of corticotropin-releasing factor (CRF or CRH) from the hypothalamus. This stimulates the pituitary to secrete adreno-corticotropin, which in turn promotes cortisol release from the adrenal gland, further stimulating the SNS. Cortisol then suppresses the HPA axis (acting via negative feedback inhibition on the hypothalamus, pituitary, and hippocampus), which leads to homeostasis. Investigation of these two major stress systems—the catecholamine system and the HPA axis—has been the focus of research with children and young people.

There is evidence for disruption to the catecholamine system in traumatized children with symptoms of PTSD. For example, after traffic accidents, children with PTSD show higher morning noradrenaline at 1 and 6 months posttrauma (Pervanidou *et al.*, 2007). Children with abuse-related PTSD also show higher 24-hour urinary adrenaline or noradrenaline (De Bellis *et al.*, 1999a, b). In line with a sensitized adrenergic response, Scheeringa *et al.* (2004) found that preschool children with PTSD showed increased heart rate in response to trauma reminders, compared to nontraumatized controls. Follow-up studies of hospitalized injured children have shown that children who go on to develop PTSD have higher heart rates at admission (Kassam-Adams *et al.*, 2005; Bryant *et al.*, 2007; de Young *et al.*, 2011).

Alteration in functioning of the HPA axis appears to differ according to time since exposure, and to whether the child has recently been exposed to further stress or trauma. In acutely traumatized children, there is evidence for hypersecretion of cortisol (e.g. Weems & Carrion, 2007), whereas young people with chronic PTSD show lower resting baseline levels of cortisol (e.g. Goenjian *et al.*, 2003), although findings are mixed (see Kirsch *et al.* (2011) for a recent review). Chronically maltreated children show a blunted cortisol reactivity to psychosocial stress (MacMillan *et al.*, 2009; Ouellet-Morin *et al.*, 2011), and lower cortisol responses are in turn associated with greater social and behavioral problems (Ouellet-Morin *et al.*, 2011). The suggestion is that compensatory downregulation of the HPA axis occurs in children with chronic PTSD, leading to an increasingly maladaptive response over time.

Consistent with disruption to the HPA axis, reductions in the volume of the hippocampus have been reported in children with

PTSD relative to nonexposed controls (Carrion *et al.*, 2010). This is consistent with convincing meta-analytic evidence for reduced hippocampal volume in adults with PTSD (Woon & Hedges, 2011). However, several studies have reported significantly larger hippocampal volume in children with PTSD (e.g. Tupler and de Bellis, 2006), and further imaging research is needed.

The neural basis of emotional processing in trauma-exposed children has been investigated using fMRI methods. McCrory *et al.* (2013) found increased right amygdala activation in response to preattentively presented emotional faces (angry and happy) among maltreated children, compared to matched controls. This enhanced neural response implies differences in very early (preconscious) processing of affect among maltreated children relative to healthy controls.

Cognitive processes and models

Cognitive models of anxiety predict attention bias toward threat among anxious individuals. Experimental investigations using the dot-probe task have generally (although not always) demonstrated attention bias toward threat in anxious children (e.g. Taghavi *et al.*, 1999; Roy *et al.*, 2008; see Chapter 60). Since hypervigilance for danger characterizes the phenomenology of PTSD, it is predicted that attention bias to threat can be demonstrated experimentally among children with PTSD. However, findings are mixed. For example, relative to healthy controls, young people with PTSD have shown attention *toward* threat (e.g. Moradi *et al.*, 1999), *away* from threat (Pine *et al.*, 2005), or no bias (Dalgleish *et al.*, 2003). A recent very large community study ($N = 1774$; Salum *et al.*, 2013) found attention bias toward threat in young people with high internalizing symptoms (including PTSD), alongside bias away from threat in young people with phobic disorders. Interpretation of discrepant findings is limited by sampling and methodological differences between studies (Dalgleish *et al.*, 2005), and further work is needed to investigate attentional vigilance and avoidance in PTSD (Schechter *et al.*, 2012).

Higher order cognitive processes including memory and appraisals are fundamental to cognitive models of PTSD. Under Ehlers and Clark's (2000) cognitive model, persistent PTSD is maintained by the disjointed nature of the trauma memory; misappraisals of the trauma and its sequelae and maladaptive coping strategies. The applicability to children of cognitive models of PTSD has been tested in a series of carefully designed prospective studies. There is now considerable evidence from independent research groups that the initial unhelpful appraisals of trauma-exposed children account for substantial variance in PTSD symptoms 6 months later (see page above). As predicted by cognitive models, the particular characteristics of trauma memories—specifically their degree of disorganization—have recently been found to distinguish trauma-exposed children with ASD from those without ASD (Salmond *et al.*, 2011). Consistent with cognitive models, unhelpful coping strategies (such as thought suppression, rumination, cognitive avoidance) are strongly related to PTSD symptom severity in both

cross-sectional and longitudinal studies (e.g. Meiser-Stedman *et al.*, 2005; Stallard and Smith, 2007). This has clear implications for treatment (see page below).

Brewin and colleagues' (Brewin *et al.*, 1996; Brewin, 2001) dual representation theory of PTSD proposes that there are two types of trauma memory, stored in different representational formats: verbally accessible memory (VAM) supports ordinary autobiographical memories; situationally accessible memory (SAM) supports specific trauma-related dreams and flashbacks. An update to this structural model (Brewin *et al.*, 2010b) describes a contextual memory system and a sensory memory system, and specifies how each system has a distinct neural basis. Recent fMRI work with adults has supported the prediction from dual representational theory that VAMs are associated with activity in the dorsal visual stream rather than the medial temporal lobe (Whalley *et al.*, 2013), but this remains untested with children and young people.

Treatment

There is an increasing number of RCTs of treatments for PTSD (or subthreshold posttraumatic stress symptoms) in children and adolescents. A number of expert reviews and systematic reviews summarize this published evidence (Feeny *et al.*, 2004; Stallard, 2006; Silverman *et al.*, 2008; Gillies *et al.*, 2012; Forman-Hoffman *et al.*, 2013). Recent professional guidelines also utilize the RCT evidence and provide expert clinical consensus when trial evidence is lacking (American Academy of Child and Adolescent Psychiatry, 2010; NICE, 2005). All published international guidelines and reviews recommend trauma-focused cognitive behavioral therapy (TF-CBT) for children and young people with PTSD. Other treatments are available but none is as thoroughly evaluated as TF-CBT. An overview of the current evidence base is provided below.

Early interventions

While prevention is seen as better than cure, in respect of PTSD this has to be seen as preventing the occurrence of traumatic events or children's exposure to them. Early intervention would be attractive if it could be shown that it prevented later development of PTSD or other disorders. Critical incident stress debriefing was originally developed by Mitchell (1983) to prevent traumatic stress reactions in fire-fighters. These were people who worked and trained together, and use was made of the dynamics and support of the existing group. At some point, other professionals extended debriefing to civilian survivors of traumatic incidents, and also to children. Thus, a single, one-off intervention subsumed under the heading "debriefing" was born. However, subsequent studies with trauma-exposed adults generally found that debriefing is not very effective in preventing later PTSD, although the survivors appreciated being offered help. Several RCTs of single-session debriefing, delivered universally to all trauma-exposed children and young people,

have now been carried out (Stallard & Salter, 2003; Stallard *et al.*, 2006; Kenardy *et al.*, 2008; Zehnder *et al.*, 2010). None of them has demonstrated that debriefing prevents PTSD. There is evidence from work with trauma-exposed adults that debriefing may be harmful in that it slows down natural recovery (Mayou *et al.*, 2000). While there is no evidence that debriefing is harmful to children, it is now widely agreed that such one-off, brief, individually administered interventions do not help reduce later PTSD.

Given the lack of evidence for single-session debriefing, alternative approaches to early intervention have been trialed recently. Rather than single-session intervention for everyone exposed to trauma, multiple-session early interventions for symptomatic children have been tested using a “screen and intervene” model. For example, Kassam-Adams *et al.* (2011) report that a screen-and-intervene approach was feasible to implement within a pediatric hospital setting. Berkowitz *et al.* (2011) report positive RCT findings for an early intervention screen-and-intervene approach for children (7–17 years old) exposed to a variety of traumatic events. A four-session intervention, the Child and Family Traumatic Stress Intervention (CFTSI), was flexibly delivered to parents and symptomatic children in the first 2 months posttrauma, and included psychoeducation, techniques to improve family communication and behavioral and cognitive skills teaching (coping enhancement). Postintervention, and at 6-month follow-up, there were significant and meaningful improvements in PTSD among those in the CFTSI group.

These studies show that although universal single-session early interventions have not been helpful, screen-and-intervene approaches appear feasible and promising. In reality, it often takes several weeks to implement an early intervention program. That is not to say that one should do nothing in the first few days posttrauma. Parents and teachers need better guidance on what to say to children early on, and how to say it, so that any normal healing processes are not compromised. The WHO Inter Agency Standing Committee (2007) and the US National Child Traumatic Stress Network (Brymer *et al.*, 2006) have issued guidance for “Psychological First Aid.” Both emphasize the need for good social support to child survivors and families in the first few weeks, although these interventions have yet to be empirically tested (Yule, 2008).

Trauma-focused CBT (TF-CBT) for persistent PTSD

Systematic reviews of interventions for children with PTSD are in good agreement that, as with adults, TF-CBT is currently the best supported treatment. Components of TF-CBT include psychoeducation about PTSD, developing a trauma narrative, identifying and updating problematic meanings and misappraisals, dropping unhelpful cognitive, and behavioral avoidance, *in vivo* exposure to reminders, behavioral activation, arousal management (e.g. learning relaxation skills) and work with parents.

PTSD and single-event traumas

To date, a small number of randomized controlled trials of psychological interventions with children who developed PTSD symptoms as a result of single-event traumas have been reported (Chemtob *et al.*, 2002; Stein *et al.*, 2002; Smith *et al.*, 2007; Gilboa-Schechtman *et al.*, 2010; Nixon *et al.*, 2012).

Group-based CBT in schools has been shown to be effective. After Hurricane Iniki hit Hawaii, all elementary school children were screened for serious stress reactions and the high-risk group of 248 children were randomly assigned to one of three treatments (Chemtob *et al.*, 2002). This consisted of four sessions delivered either individually or in groups. The specially developed, manualized treatment had many elements in common with other CBT approaches. Both individual and group treatment had equally good results but more children dropped out of individual than group treatment. Stein *et al.* (2002) report an RCT in which 61 children who had been exposed to violence were given 10 sessions of group CBT and compared with 65 children who were allocated to a delayed intervention condition. At 3 months posttreatment, the treated group had significantly lower scores on the Child PTSD Symptom Scale (CPSS) (Foa *et al.*, 2000). Significant differences were also found on measures of depression and psychosocial dysfunction. Teacher-rated behavioral difficulties did not reflect improvement. The delayed treatment group then made significant PTSD improvement following treatment. In both these studies, children were recruited from school-based screening rather than from clinic-referred children. Not all participants had diagnoses of PTSD.

More recent RCTs have shown individual TF-CBT and Prolonged Exposure to be highly effective in treating PTSD following single-incident trauma. For example, Smith *et al.* (2007) compared TF-CBT to a Wait List comparison condition for $N=24$ children who developed clinician-validated PTSD following assault or RTA. Treatment was adapted from Ehlers and Clark's cognitive therapy treatment protocol, based on Ehlers and Clark's (2000) model of PTSD, and included a variety of components which were aimed at reducing known maintaining factors (see above). Posttreatment, 11 of the 12 young people who received TF-CBT no longer met criteria for PTSD compared with 5 of the 12 on the wait list. Treated children also showed significant reductions in symptoms of depression and anxiety. Improvements remained at 6-month follow-up. As predicted, therapeutic gains in the TF-CBT group were partially mediated via changes in maladaptive cognitions.

Therapeutic exposure to the trauma memory is a key component of most forms of TF-CBT. Two recent RCTs have tested whether such exposure is really essential. Gilboa-Schechtman *et al.* (2010) directly compared 12–15 sessions of prolonged exposure with 15–18 sessions of psychodynamic therapy in a randomized controlled trial (RCT) for adolescents ($N=38$). Both treatments were associated with reductions in PTSD and depression at posttreatment and at follow-up. Prolonged exposure was superior to psychodynamic therapy in reducing PTSD symptoms and depression symptoms at posttreatment and at

6-month follow-up. Of the adolescents who completed the treatment, 87% (prolonged exposure) and 47% (psychodynamic therapy) were free of PTSD diagnosis posttreatment. Results imply that exposure to the trauma memory is an important component of effective treatment.

In contrast, the RCT by Nixon *et al.* (2012) showed that a form of cognitive therapy which explicitly precluded exposure was highly efficacious for adolescents suffering from PTSD. Thirty-three adolescents who had developed PTSD (or subsyndromal PTSD symptoms) after exposure to single-incident trauma such as road traffic accidents and assaults were included. One group had nine sessions of cognitive therapy (including anxiety management, cognitive restructuring, and working with parents); the other group had nine sessions of TF-CBT (including the same components as well as imaginal and *in vivo* exposure). In the cognitive therapy arm, 90% of completers ($N=10$) and 56% of the intention-to-treat samples ($N=16$) were diagnosis-free at posttreatment. In the CBT arm, 91% of completers ($N=11$) and 65% of the intention-to-treat samples ($N=17$) were diagnosis free at posttreatment. Differences between cognitive therapy and TF-CBT were not significant. Results of this RCT imply that exposure to the trauma memory through imaginal reliving is not necessary for therapeutic effect, and that techniques of modifying trauma-related misappraisals and dysfunctional beliefs may be equally effective. An earlier study (Smith *et al.*, 2007) found that changes in trauma-related misappraisals mediated the effect of TF-CBT (relative to a waiting list control condition) on PTSD symptoms. The relative contribution of exposure techniques and cognitive techniques to symptom reduction is not yet clear, but it may be that their careful integration is important to successful outcome. Although TF-CBT is a powerful treatment, further investigations of mediators and moderators will help to refine and enhance future protocols.

Thus, TF-CBT has been found effective for treating stress reactions after single-incident traumas. Moreover, it has been shown that it improves anxiety and depression as well. The effects appear to last and it seems to be effective when delivered in groups as well as individually. However, as Forman-Hoffman *et al.* (2013) point out in their comparative effectiveness review, the evidence remains small, sample sizes in published RCTs are small to modest and further work is needed.

Trauma-focused-CBT with preschool children

TF-CBT has been successfully adapted to help young, 3-to-6-year-old children, suffering PTSD (Scheeringa *et al.*, 2011). Adaptions include greater parental involvement, more emphasis on behavioral management training and relaxation techniques, use of visual aids (e.g. cartoons for psych-education), and imaginative use of drawing and playing to complete imaginal reliving. Scheeringa *et al.* (2011) undertook a randomized trial with 64 children given either a 12-session manualized TF-CBT or placed on a waiting list for 12 weeks. Interestingly, TF-CBT reduced

PTSD with large effect size, but did not immediately reduce depression, separation anxiety, or oppositional disorders. These were found to improve after the waiting group received treatment and the gains on PTSD increased at 6-month follow-up. Thus therapy based on TF-CBT principles, suitably adapted to young children's development, is feasible to deliver and appears effective with preschool children.

PTSD and child sexual abuse

In recent years, many of the reactions children develop to sexual abuse have been formulated as part of a spectrum of post-traumatic stress reactions (see Chapter 30). This has resulted in a number of therapeutic trials of CBT to treat these reactions, including full PTSD. Most published RCTs of TF-CBT report outcomes for children traumatized by sexual abuse. For example, of 21 studies included in Silverman *et al.*'s (2008) review of evidence-based psychosocial treatment, 11 were concerned with sexual abuse. TF-CBT is now a well-established treatment for PTSD that has arisen following sexual abuse (Silverman *et al.*, 2008).

Ramchandani and Jones (2003) report a systematic review of RCTs treating a range of psychological symptoms in sexually abused children. They identified 12 RCTs—3 investigating Group CBT; 6 investigating individual CBT; 1 of adding group therapy to a family therapy intervention; and 2 comparing individual (non-CBT) therapy with group therapy. The dependent (outcome) measures were very varied, and only four studies looked at recognized, specific measures of PTSD. Nevertheless, TF-CBT was recommended as the treatment of choice for PTSD in sexually abused children.

In the largest study to date, Cohen *et al.* (2004) carried out a multisite RCT of TF-CBT compared to child-centered therapy for symptoms of PTSD and other problems in $N=229$ sexually abused children (8–14 years old). TF-CBT was associated with significant and clinically meaningful improvements in PTSD symptoms, as well as depression, anxiety, and externalizing problems. Treatment gains were maintained at 6- and 12-month follow-up. These findings were in line with previous RCTs from Cohen's group and others (Cohen & Mannarino, 1996, 1997, 1998; Deblinger *et al.*, 1996, 2001, 1997; King *et al.*, 2000), which provide convincing evidence of the efficacy of TF-CBT across a variety of settings.

The relative importance of exposure-based therapy components was investigated recently by Deblinger *et al.* (2011) in an evaluation of TF-CBT for children who developed PTSD symptoms following sexual abuse. They tested directly whether the development of a trauma narrative was necessary for symptom reduction. About 210 children (4–11 years old) and their parents were randomized to one of four conditions: eight sessions with or without a trauma narrative component, or 16 sessions with or without a trauma narrative. Consistent with their earlier studies, they report a large effect for TF-CBT across all treatment conditions (effect size across all outcome measures and all treatment

arms, $d = 0.94$) However, children allocated to the conditions that included a trauma narrative component reported less fear associated with thinking or talking about the abuse, and less general anxiety, compared with children in the conditions that did not include a trauma narrative component. Many of the children in the trauma narrative conditions reported that talking about the abuse specifically was the most important part of therapy. In contrast, parents assigned to the 16-session, no trauma narrative condition reported greater increases in effective parenting practices and fewer externalizing child behavioral problems. This study is therefore an important step toward the delivery of psychological therapies that are tailored toward young children's specific profile of posttrauma difficulties.

Mannarino *et al.* (2012) reported 6- and 12-month follow-up of 158 children (4–11 years) treated by TF-CBT after child sexual abuse. The study contrasted a variant of their version of TF-CBT with or without a module on trauma narrative. It was found that the initial gains in both groups were maintained. Initial higher levels of internalizing and depressive symptoms predicted those whose PTSD did not improve.

The immediate and long-term psychological effects of childhood sexual abuse are many, varied and serious (see Chapter 30). The studies reviewed by Ramchandani and Jones (2003), and Silverman *et al.* (2008) strongly indicate that TF-CBT is currently the treatment of choice, although there is clearly a great need for further RCTs. As Feeny *et al.* (2004) note, child survivors of sexual abuse may present a different symptom picture to that of children exposed to single-incident traumas and so generalization of findings to those may be problematic (see also American Academy of Child and Adolescent Psychiatry, 2010).

Other approaches to treatment

Eye movement desensitization and reprocessing (EMDR)

Eye movement desensitization and reprocessing (EMDR) was discovered by chance by Shapiro (2001) and has been applied with good results with adults (NICE, 2005). EMDR is an empirical treatment with little theoretical underpinning. The detailed protocols for treatment include a careful history and ensuring that the patient can have a break if the intrusions during treatment prove too frightening. Essentially, the child is asked to focus on a traumatic memory while simultaneously following the moving fingers of the therapist. This “dual attention” task is thought to help the child confront the frightening memory and so “process” the emotional reaction to that memory. There is some controversy about the active components of treatment in EMDR. For example, dismantling studies (e.g. Pitman *et al.*, 1996) have not provided evidence for a cardinal role for saccadic eye movements. The overlap between treatment components of CBT and EMDR (e.g. therapeutic exposure) have led some to suggest that the mechanisms of change may be broadly similar in both approaches.

Two case series illustrate the use of EMDR with children. Hensel (2009) reported a consecutive series of 36 children aged

1 year 9 months to 18 years. About 32 received an average of three EMDR sessions and reduction in distress both immediately after treatment and at follow-up. Ribchester *et al.* (2010) used EMDR with 11 children who developed PTSD after road traffic accidents. None met criteria for PTSD on standardized assessments after an average of only 2.4 sessions. Significant improvements in PTSD, anxiety, and depression were found both immediately after treatment and at follow-up. Treatment was associated with a significant trauma-specific reduction in attentional bias on the modified Stroop task, with results apparent both immediately after therapy and at follow-up. This case series suggests that EMDR may produce reductions in attentional bias and so indicates ways of tapping the processes behind the change in posttraumatic stress.

DeRoos *et al.* (2004) reported an RCT involving 52 children following the 2000 Enschede (Netherlands) fireworks disaster. Both EMDR and CBT produced significant lowering of stress symptoms, with EMDR doing slightly better in fewer sessions. Ahmad *et al.* (2007) similarly reported significantly lower stress scores after EMDR, relative to wait list in an RCT involving 33 children diagnosed with PTSD. Kemp *et al.* (2010) report a pilot RCT involving 13 children receiving four sessions of EMDR compared with 14 children on a 6-week wait list control. EMDR was significantly better than the comparison condition, and treatment gains were maintained at 12-month follow-up.

While the NICE (2005) report found good evidence from RCTs with adults to be able to make a firm recommendation that it be available to patients in the UK NHS, the evidence base with children remains less robust. Even despite the lack of theoretical basis for EMDR, it appears that it can work very quickly and so should be considered as a possible treatment for children.

Narrative exposure therapy (NET)

Arising in part from South American methods of helping victims of torture and in part from a thoroughgoing analysis of the neurobiology of autobiographical memory and ways of completing fragmented memories, Schauer *et al.* (2004) have developed Narrative Exposure Therapy and used it in RCTs with adult refugees in the Sudan (Neuner *et al.*, 2004). It has now been evaluated as a treatment for PTSD in war-affected children in Sri Lanka (Onyut *et al.*, 2005; Schauer *et al.*, 2005; Neuner *et al.*, 2006), child soldiers in Uganda (Ertl *et al.*, 2011) and for refugee children who settled in Germany (Ruf *et al.*, 2010). NET is associated in these RCTs with significant improvements in PTSD symptoms and functioning, relative to wait list controls and active comparison conditions. The technique has the advantage that children who have experienced multiple trauma can discuss memories of all of them. The disadvantage is that as the intervention is at present only given individually, it is difficult to reach many of the child survivors of conflicts. To date, there are no published RCTs other than those undertaken by the developers of the model.

Structured writing

Pennebaker (1995) has long demonstrated that writing about emotional events in structured ways can have very positive effects. Typically, participants are asked to write about their emotions for brief periods, usually 3–6 times for 15 min on each occasion (see review by Frattaroli (2006) of 146 emotional disclosure studies). Van der Oord *et al.* (2010) included a structured writing component within a broader treatment approach. Children typed their story into a computer (or were helped to do so). A case series of 23 children (8–18 years) received an average of 5.5 sessions of cognitive behavioral writing therapy (CBWT) and showed significant reductions in stress reactions at 6-month follow-up, indicating that CBWT is a promising technique.

Kalantari *et al.* (2012) used the Children and War Foundation's Writing for Recovery manual in an RCT of 61 bereaved Afghani adolescents. They followed the structured emotional writing protocol for six sessions of 15 min each. The treated group showed a highly significant drop in scores on the Child Traumatic Grief Inventory, indicating that this promises to be an effective group intervention for bereaved children and adolescents after disasters.

Medication

Despite the paucity of proper trials on children by pharmaceutical companies in developing psychotropic drugs, many children are indeed prescribed such medication (often by general practitioners rather than child specialists) following traumas. Given the recent disclosures that trials of selective serotonin reuptake inhibitors (SSRIs) increased the risk of self-harm in depressed adolescents, one's confidence in the use of medication with children is not great. Indeed, the NICE (2005) Guideline Development Group found no study that met its stringent criteria. Medication is not recommended as a treatment for PTSD in children in the United Kingdom (NICE, 2005). Guidelines from the American Association for Child and Adolescent Psychiatry (AACAP, 2010) recommend that SSRIs, and other medications may be considered in the treatment of PTSD.

Contingency planning/school-based interventions after mass incidents

When trauma affects a large number of children at once, as in an accident at school, then a public health approach to dealing with the emergency is required (Pynoos *et al.*, 1995). Schools need to plan ahead not only to deal with large-scale disasters, but also to respond to the needs of children after threatening incidents that affect only a few of them. There are now a number of texts written especially for schools to help them develop contingency plans to deal with the effects of a disaster (Johnson, 1993; Klingman, 1993; Yule & Gold, 1993).

There is a small but growing literature suggesting that TF-CBT can be effective when delivered by education professionals in schools, or by community-based clinicians for patients referred via standard clinical pathways. For example, in the aftermath

of Hurricane Katrina, Jaycox *et al.* (2010) screened nearly 700 schoolchildren and identified 195 with elevated symptoms of PTSD. These children were then invited either to participate in a school-based group CBT program or to attend a local mental health clinic and receive TF-CBT. While both treatments were effective in reducing PTSD symptoms, TF-CBT showed marginally better outcomes. However, there was a high dropout rate and no intention to treat analysis was reported. Importantly, 98% of the children who were offered the school-based program accepted treatment, and 91% completed treatment. In contrast, only 37% of children offered TF-CBT at the clinic started treatment, and only 9% completed. Thus, treatment location as opposed to treatment type appeared to have a large influence on treatment uptake, and some families asked for the TF-CBT to be delivered at the school. School-based treatment may be more convenient and/or less stigmatizing for some families.

Most developed countries have well-established plans to deal with major civil emergencies. Increasingly, these include a psychosocial or mental health component and it is advisable for child and adolescent mental health services to be involved in the planning (Canterbury & Yule, 1999). UN agencies are increasingly prepared to meet the mental health needs of children after war and major disasters (Machel, 2001) and again mental health services need to collaborate with other agencies to meet such needs. In considering the need to plan for "Mental Health in Complex Emergencies," Mollica *et al.* (2004) argued that all countries should develop plans to meet mental health sequelae of disasters. Since most disasters occur in developing countries, it is vital that appropriate assessment and intervention tools are developed that are culturally appropriate. It is also essential that such interventions are properly evaluated. Research is essential, not a luxury and that message needs to be accepted by nongovernmental organizations (NGOs) responding to disasters. Given that disasters happen with great frequency, then by planning ahead, proper consideration can be given to the ethical aspects of intervening soon after a crisis. Unless one does evaluate early interventions responsibly, significant resources are wasted and survivors suffer unnecessarily.

The Children and War Foundation has developed measures that can be used in large-scale emergencies as well as manuals for helping groups of children (Yule *et al.*, 2013). Case series and RCTs demonstrate that the Teaching Recovery Techniques manual produces significant decline in stress reactions. Notably, Barron *et al.* (2012) and Quota *et al.* (2012) both worked with traumatized children in Palestine and produced worthwhile improvements, despite the ongoing nature of the war there.

The World Health Organization and the Inter Agency Standing Committee (IASC) have produced guidance on how and when to intervene after disasters. These have achieved considerable agreement across many NGOs, but interrater agreement is not the same as validity and much more evidence is required before such guidelines can be accepted at face value (Yule, 2008). Fortunately, there are now a number of reviews that indicate

empirical approaches to developing better interventions after wars and disasters (see, for example, Peltonen & Punamaki, 2010; Betancourt, 2011; Panter-Brick *et al.*, 2011; Tol *et al.*, 2011; Jordans *et al.*, 2011). Together, these initiatives should result in a fundamental rethink on how countries respond to children affected by wars and disasters and so result in much less distress.

Conclusions and recommendations

Considerable progress has been made in the past 25 years in understanding the nature of posttraumatic stress reactions in young people. There are now a number of empirically validated interventions both for individuals and groups. Cognitive models are proving a fertile source for understanding the mechanisms that give rise to serious and chronic reactions. It is better realized that whereas the point prevalence of full PTSD may be relatively small in child populations, the incidence following particular traumatic events can be so high as to overwhelm local mental health resources.

More recently, there has been greater emphasis on understanding stress reactions in young children, but much remains to be done. There is a paucity of well-designed studies of stress reactions in children and as the long-term consequences are better understood, the need for greater investment in research in this area is all too apparent.

CHAPTER 60

Anxiety disorders

Daniel S. Pine¹ and Rachel G. Klein²

¹Section on Development and Affective Neuroscience, National Institute of Mental Health (NIMH) Intramural Research Program, Bethesda, MD, USA

²The Child Study Center at New York University Langone Medical Center, Department of Child and Adolescent Psychiatry, New York University School of Medicine, NY, USA

Introduction

The chapter reviews anxiety disorders, which include specific phobias, separation anxiety disorder, social anxiety disorder, generalized anxiety disorder, panic disorder, and agoraphobia. The first four anxiety disorders are unique in at least one respect. The features that define them represent aspects of normal development, raising questions on the boundary between normal and pathological anxiety.

Fear and anxiety play important roles in functioning, and have major evolutionary significance; they enable the awareness of danger, and prepare the individual to avoid threat. The term *fear* refers to a state elicited by an immediately present specific object or situation that is capable of harm or danger. *Anxiety* resembles fear but occurs in situations that are not acutely dangerous, but which are experienced as such. Although adaptive, fear and anxiety may become pathological when they are provoked by objects or situations that are not legitimately harmful or threatening or when they limit the person's functioning.

Diagnosis

Boundaries between normal and pathological anxiety are not clear-cut, and there is no defining point at which we can aver that pathology begins. Clearly, extreme anxiety is readily recognized as abnormal in the same way that extreme intellectual disability is readily distinguished from normal intelligence. For milder expressions of anxiety, however, decisions are more difficult, since anxiety is adaptive in some contexts or developmental periods. The dilemma is not inconsequential because the identification of pathological anxiety calls for the development and delivery of effective treatments, as well as efforts to prevent, and hopefully cure, the disorders. Distinguishing pathological from normal anxiety requires the clinician to recognize a departure

from anxiety's adaptive role in functioning, ultimately based on judgments about the presence of clinically meaningful avoidance or distress.

At any age, anxiety is pathologic when it interferes with adaptive behavior. Parents and clinicians are often quick to recognize markedly impairing anxiety that causes significant avoidance, but anxiety may be pathological under other circumstances, even without the presence of manifest functional impairment, if anxiety causes clinically significant distress. It is useful to consider a child's ability to recover from anxiety, and to remain anxiety-free, when the anxiety provoking situation is absent or removed, since failure to modify appropriately one's responses to changing circumstances is a hallmark of psychopathology.

Nosology

A major shift occurred in 1980, with the publication of DSM-III, which introduced several anxiety disorders. There have been objections to having multiple anxiety disorders in nosology, because of inadequately clear definitional boundaries among the disorders. In the future, the hope is that distinctions among anxiety disorders will be informed by data on outcome (Pine *et al.*, 1998, 2001), genetics, or psychobiology (Pine & Cohen, 2002). This was not yet possible for the DSM-5 and ICD-11. DSM-IV, which appeared in 1994, eliminated two DSM-III pediatric anxiety disorders, avoidant disorder and overanxious disorder. This change reflected the principle that common diagnostic standards should be applied from childhood through adulthood, with age-relevant clinical examples, an approach that remains in DSM-5. ICD-10 and DSM-IV were broadly similar but differed in the handling of comorbidity and in the placement of obsessive compulsive disorder (OCD) and posttraumatic stress disorder (PTSD); DSM-5 brings greater alignment with the ICD. Both ICD-11 and DSM-5 place OCD and PTSD outside the anxiety disorders. Otherwise, there have been only minor changes in the anxiety disorders.

Specific conditions

Specific phobia

This diagnosis is defined by marked, unreasonable fear of specific objects or situations that do not pose actual danger, such as various animals or situations. Although unreasonable fears are common, they are diagnosable only when they cause distress or avoidance, severe enough to interfere with normal activities. Phobic disorders may begin at any age, but onset is typically in childhood, and usually do not persist through adolescence and adulthood (Fyer, 1998; Pine *et al.*, 1998).

Separation anxiety disorder

Relative to other anxiety disorders, separation anxiety disorder has an unusually skewed age distribution, typically occurring before the age of 18 and usually, but not always, remitting before adulthood. While separation anxiety is part of normal early-childhood development, separation anxiety disorder reflects pathology, which interferes with functioning. Typically, the child avoids activities that require ordinary separation from caretakers, such as play dates in friends' homes. Children with separation anxiety disorder may display symptoms that defy logic. For example, a child who attends school comfortably may face extreme distress when attending a social gathering without a parent. Clinical descriptions of "school phobia" typically do not, strictly speaking, identify children with a phobia. Such children often suffer from an extreme form of separation anxiety. Though unusual, separation anxiety may be episodic, with periods of impairing anxiety that remit, and may reoccur. Strikingly, severe separation anxiety may develop in children and adolescents who, previously, had not evidenced concerns about separation.

Social anxiety disorder

In social anxiety disorder, the classic presentation involves concerns about being perceived as acting foolish or stupid. Some children may fail to report these concerns. The diagnosis is then based on observations that these children appear self-conscious and uncomfortable in social settings. To be diagnosed, children must experience discomfort with peers, not only with adults, and anxiety cannot be due to impaired capacity for socialization, as occurs in autism spectrum disorders. This aspect of classification can complicate diagnosis, as children with autism spectrum disorders may receive the diagnosis of social anxiety disorder, provided their anxiety in social situations can be distinguished from the dysfunction they exhibit due to impaired socialization.

Generalized anxiety disorder

Generalized anxiety disorder is characterized by a variety of worries. Children often worry about their ability to succeed, often related to schoolwork, appearance, or future, and because of their self-doubt, they strive for perfection. The age-of-onset is poorly understood, with the available evidence placing peak onset in late adolescence or early adulthood. Relative to

other anxiety disorders, generalized anxiety disorder is more likely to occur with other psychopathology, to the point where the disorder rarely occurs on its own. The relationship with other anxiety disorders and with major depressive disorder is particularly robust (Costello *et al.*, 2002; Kessler *et al.*, 2002).

Panic disorder

Panic disorder is characterized by the repeated experience of unprovoked, spontaneous, panic attacks, consisting of fear of impending doom or danger to oneself, accompanied by physical symptoms. Panic disorder is rare before puberty. Typically, the disorder begins with an initial spontaneous panic attack, occurring around late adolescence. Most individuals suffer only a few instances of spontaneous panics. Progression to recurring attacks and eventual full-blown panic disorder is the exception, but when it happens, this typically occurs by early adulthood (Pine *et al.*, 1998).

Agoraphobia

Agoraphobia refers to extreme fear and avoidance of independent travel. In DSM-IV, agoraphobia was an aspect of panic disorder, because it typically develops in individuals with panic disorder. ICD-10 did not follow this convention, nor does DSM-5. Since panic disorder is rare in prepubertal children, minimal work examines pediatric agoraphobia, which is believed also to be rare. Children with separation anxiety, for example, may fear traveling on their own.

Developmental fluctuations

Across cultures, there are similar age-related fluctuations in fears and anxiety. This consistency suggests that age-related changes in anxiety represent a core aspect of human development (Ollendick *et al.*, 1996; Ingman *et al.*, 1999). However, beyond this research on typical fears, cross-cultural differences in the rates of anxiety disorders have not been addressed sufficiently. When it does occur, the onset of pathological anxiety mimics developmental fluctuations in normal fears that are observed across cultures. Thus, fears of animals regularly begin in early childhood, so do specific phobias. Fears of separation also first manifests in early childhood, and separation anxiety disorder exhibits a particular high prevalence in children only a few years beyond this developmental stage (Pine *et al.*, 1998). Similarly, social concerns typically emerge as part of normal adolescent development (Ollendick & Hirshfeld-Becker, 2002), virtually coinciding with a rise in the incidence of social anxiety disorder.

Rates of anxiety, as well as the expression of anxiety, vary across development. Changes may reflect children's changing capacities with cognitive maturation, the effects of changing social contexts, which expose children to novel forms of stress, or rapid changes in biology that occur at puberty. For example, developmental manifestations of social anxiety change from a pattern of "high reactivity" during infancy (Fox *et al.*, 2005), to

“behavioral inhibition” in childhood, and ultimately to social anxiety disorder in adolescence (Clauss & Blackford, 2012).

Comorbidity

Comorbidity is an important clinical feature since it has been shown to entail relatively greater dysfunction. Although comorbidity is less apparent in community-based, than clinically based, studies, there is strong comorbidity across anxiety disorders in both settings. Elevated rates of co-occurring anxiety disorders raise the question whether the anxiety disorders represent distinct conditions, as opposed to variable expressions of underlying anxiety vulnerability.

There is unanimous agreement that major depression in adolescence is highly comorbid with anxiety disorders, with anxiety typically preceding the mood disorder. The strength of this relationship rivals virtually all others in developmental psychopathology (Angold *et al.*, 1999; Costello *et al.*, 2002; Costello *et al.*, 2004). Since depression is much rarer than anxiety disorders, especially in preadolescents, it follows that, among those with anxiety, the overlap with depression is not great, and that comorbidity increases with age. Some clinical studies report comorbidity between anxiety and attention deficit hyperactivity disorder (ADHD), but population-based studies do not confirm this relationship (Angold *et al.*, 1999). While some have reported comorbidity between current anxiety disorders and substance abuse or conduct disorder, these associations also are weak (Kaplow *et al.*, 2001; Rutter *et al.*, 2006). Moreover, longitudinal findings raise questions on the nature of the relationship between anxiety and either substance abuse or conduct disorder, since anxiety predicts better outcome in some children with conduct problems (Pine *et al.*, 2000). It may be that children with conduct and anxiety disorders represent a distinct clinical subgroup of conduct disorder. Although studies have not linked anxiety and learning disorders in children, it behooves clinicians to rule out learning problems, particularly in children who present with school-based anxiety.

Assessment

Efforts to systematically assess pediatric anxiety benefit from a proliferation of instruments, including paper and pencil scales, as well as multiple diagnostic interviews. Because several reviews summarize these (Brooks & Kutcher, 2003; Seligman *et al.*, 2004; Silverman & Ollendick, 2005), only an overview is provided.

Rating scales

Rating scales serve many purposes. They may screen large groups or facilitate the collection of data relatively efficiently for large studies of genetic and environmental correlates. Early rating scales, which anteceded DSM-III and ICD-10, comprised factors such as worry, physiological anxiety, and fear of bodily harm. Other scales, such as the Children's Behavior Checklist (CBCL) (Achenbach, 1991), generate a nonspecific factor

of emotional disturbance, called an “internalizing” factor. In general, these scales appear to assess constructs distinct from those assessed by newer scales. One major important clinical challenge is to differentiate between anxiety and depression based on scale scores, a challenge reflected by the single, unitary factor scale in the CBCL. The meaning of self-ratings of anxiety is further complicated by the finding that children's self-ratings often correlate poorly with parent ratings, or with symptoms of anxiety obtained from clinical interviews (RUPP, 2003). Anxiety scales may provide overall estimates of anxiety levels, but they do not provide diagnoses of specific anxiety disorder. Clinicians would be unwise to rely on scales for differential diagnosis.

Growing interest in anxiety disorders has spurred the development of more diagnostically relevant child- and parent-rated measures. Recent scales parallel the clinical definitions of anxiety disorders by providing specificity of content, so that items correspond to the clinical criteria provided in the DSM. In this vein, several scales have been devised. The Multidimensional Anxiety Scale for Children (MASC) (March *et al.*, 1997; March & Sullivan, 1999) and the Self Report for Child Anxiety Related Disorders (SCARED) (Birmaher *et al.*, 1997) have been used in many studies. They possess strong psychometric properties, and they are sensitive to treatment effects, rendering them useful in treatment studies and clinical monitoring. The Pediatric Anxiety Rating Scale (PARS) has emerged as the standard clinician-rated measure in most clinical trials and is particularly useful for assessing progress during treatment.

Diagnostic interviews

Several interviews exist, each devised to meet different purposes. The highly structured Diagnostic Interview Schedule for Children (DISC) was developed for use in epidemiological studies, to be administered by individuals without clinical training (Shaffer *et al.*, 2000), or by a computer. Support for the clinical utility is mixed, with some research documenting agreement with clinicians (Schwab-Stone *et al.*, 1996), but other studies finding unduly high rates of disorders and questionable validity (March *et al.*, 2000). The Child and Adolescent Psychiatric Assessment (CAPA) (Angold & Costello, 2000), with excellent psychometric properties, also was developed for use in epidemiological studies. Relative to the DISC, the CAPA requires more training, and has not been used as widely. The Kiddie-Schedule for Affective Disorder and Schizophrenia (K-SADS) was developed for use by clinicians, and allows full latitude of inquiry. Multiple versions exist (Kaufman *et al.*, 1997; Kaufman *et al.*, 2000), but differences are small. The Diagnostic Interview for Children and Adolescents (DICA) (Reich, 2000) is a highly structured clinical interview that has been used in various ways, including in semistructured, flexible, formats. The Anxiety Disorders Interview Schedule for Children (ADIS) was designed for clinicians. It was originally limited to the assessment of anxiety, but has been expanded to include other major disorders (Silverman *et al.*, 2001).

All of these interviews demonstrate modest to adequate test-retest reliability. The major factor informing selection concerns the availability and training of clinicians for implementation. Without highly trained clinicians, the DISC or CAPA seem the best options. Although diagnostic interviews were conceived for research purposes, they may be useful to clinicians by providing comprehensive coverage of psychopathology and are useful teaching tools.

Epidemiology

Prevalence

Most studies (Table 60.1) find that anxiety disorders are the most common pediatric mental disorders and more frequent in girls than boys. Importantly, epidemiological studies confirm that child and adolescent anxiety disorders are associated with significant impairment. Studies have followed the same individuals over extended periods of time, enabling identification of typical age of onsets and incidence (Costello *et al.*, 2004; Costello *et al.*, 2005; Copeland *et al.*, 2009; Beesdo *et al.*, 2010). In childhood, phobias and separation anxiety disorder are most prevalent, diminishing in adolescence, when social anxiety disorder becomes salient. Rates of generalized anxiety disorder generally increase later in adolescence, and panic disorder is rare before this time period.

For 6-to-12-month prevalence, anxiety disorders range from 1.8% in New Zealand (Anderson *et al.*, 1987) to 23.5% in Holland (Verhulst *et al.*, 1997), reflecting large cross-study differences. Prospective studies find much higher lifetime rates of anxiety and other disorders than studies using a single assessment with retrospective recall to estimate lifetime prevalence (Angold *et al.*, 1996; Costello *et al.*, 2003; Jaffee *et al.*, 2005).

Developmental factors may explain some cross-study differences. For example, studies finding relatively high rates of separation anxiety disorder tend to include young children, whereas those that include older children find high rates of social phobia. Nevertheless, there is marked variation even for studies performed in similar populations (e.g., two studies from Germany [Essau *et al.*, 1999; Wittchen *et al.*, 1999]). Methodological differences are likely to account for such findings. Because there is large variation in prevalence in similar cultures, it is difficult to determine how, and whether, cultural factors are influential.

Could secular changes affect rates of anxiety disorders? This possibility cannot be ruled out, but does not seem to account for discrepancies across studies, since there is no evidence suggesting time-dependent changes in young people. Similarly, could different methods for generating diagnoses, such as combining reports from different informants or relying on a single informant, contribute to cross-study differences? The low rate of informant agreement in most studies makes this a reasonable possibility. Rates of anxiety disorders consistently vary across studies as a function of the reporting source, be it children or parents, and whether their reports are combined or not (Anderson *et al.*, 1987).

Longitudinal outcome

The high proportion of affected children and their impairment has fostered concern about the long-term consequences of childhood anxiety disorders. Most anxiety assessments generate only moderate test-retest reliability. Since reliability places an upper limit on associations, outcome findings may represent lower-bound estimates of stability. Anxiety has a particularly early onset, compared to other emotional disorders such as major depression. A major source of data on early risk manifestations derives from studies of temperament, especially behavioral inhibition.

Inhibited temperament and psychopathology

Kagan and colleagues (Kagan, 1994; Kagan *et al.*, 2001) first called attention to the relationship between childhood temperament and later anxiety disorders. They identified highly reactive infants, who, as toddlers, were behaviorally inhibited and reacted with apprehension to novelty. These children are defined as high reactive during infancy and as behaviorally inhibited during toddlerhood. Studies of associations with psychopathology have been conducted in thousands of children. Inhibited temperament has been consistently linked to anxiety disorders, including separation anxiety disorder, social anxiety, and phobias, though some have reported associations with depression (Caspi *et al.*, 1996). The most compelling relationship is with social anxiety disorder. Based on the data from seven longitudinal studies, inhibited children face sevenfold increased odds of developing social anxiety disorder, relative to their uninhibited peers (Clauss & Blackford, 2012).

Stability of anxiety disorders

The clearest information about diagnostic stability emerges from community-based studies, which have obtained multiple assessments across development. The first, from Dunedin, New Zealand (Anderson *et al.*, 1987), conducted multiple assessments, from age 11 through adulthood (McGee *et al.*, 1992; Feehan *et al.*, 1993; Kim-Cohen *et al.*, 2003; Poulton *et al.*, 2009). In the first follow-up, a composite index of any mood or anxiety disorder at age 11 predicted later anxiety at age 15 for girls, but not boys (McGee *et al.*, 1992). Similar sex differences were obtained in two other prospective population studies (Costello *et al.*, 1999; Rueter *et al.*, 1999). The latter found that anxiety symptoms also predicted major depression. More recent follow-ups from the Dunedin sample, as well as others, document a pattern of moderate longitudinal continuity of anxiety disorders, but little evidence of gender-specificity or concordance between specific anxiety disorders during childhood and adulthood (Lewinsohn *et al.*, 1997; Bittner *et al.*, 2004; Copeland *et al.*, 2009; Beesdo *et al.*, 2010). Other work finds longitudinal specificity of social anxiety disorder across adolescence, but not of separation anxiety disorder (Hayward *et al.*, 1998). Perhaps the strongest evidence of long-term diagnostic specificity derives from the New York longitudinal study, which

Table 60.1 Prevalence (%) of anxiety disorders in children, adolescents, and adults followed prospectively.

found distinct longitudinal patterns for the course of pediatric separation anxiety disorder, social phobia, and specific phobia from adolescence into early adulthood (Pine *et al.*, 1998). In contrast, there was little stability of overanxious disorder (replaced by Generalized Anxiety Disorder in the DSM-IV and DSM-5), from early to late adolescence (Pine *et al.*, 1998).

Beyond community-based studies, a prospective longitudinal study of offspring of referred parents with major depression or panic disorder found that specific phobias and overanxious disorder, but not separation anxiety disorder, incurred a two-to-four increase of major depression at follow-up (Weissman *et al.*, 1997). In such high-risk studies, the children's comorbidity and outcome patterns are expected to be relatively free of referral biases, but they do not eliminate referral biases of parents (Breslau *et al.*, 1987). Other findings from clinical samples (Klein, 1995; Last *et al.*, 1997; Aschenbrand *et al.*, 2003) confirm the generally good outcome for most youth with anxiety disorders, although a minority may experience significant negative psychiatric outcomes (Klein, 1995). Also, these clinical studies provide some support for a connection between separation anxiety disorder and later-onset panic disorder.

In conclusion, longitudinal studies point to several clinical observations. There is only moderate stability in pediatric

anxiety, so that most affected children will be free of anxiety disorders in adulthood. However, since most adults with anxiety disorders, as well as those with mood disorders, will have had a childhood history of anxiety disorders, childhood anxiety disorders do increase risk.

Risk factors

Due to referral biases, epidemiological studies are the best source of information about risk. However, when there is inconsistent or insufficient data, we also note findings from clinical studies. In epidemiological reports, girls have higher rates than boys of most anxiety disorders, occurring as early as age six (Lewinsohn *et al.*, 1997). Anxiety also may have greater long-term impact in girls than boys (McGee *et al.*, 1992; Costello *et al.*, 1999), but findings are not unanimous (Pine *et al.*, 1998).

Social stress

Anxiety has been linked to a range of life events, but there is little consensus regarding influential environmental factors. These include economic disadvantage, stressful life events, family dysfunction, single-parent households, and low parental

education. However, relationships are neither strong nor consistent. The lack of relationships between anxiety and social factors is not due to the inability of environmental features to relate to pediatric mental disorders, since they play a clear role in conduct disorder (McGee *et al.*, 1992). Thus, a recent study, using a quasi-experimental design, found stronger effects of poverty and its associated stresses on children's behavior problems than anxiety symptoms (Costello *et al.*, 2010). Differing stresses may relate differentially to child psychopathology. For example, stress related to social disadvantages has been shown to be associated with behavior problems, not anxiety disorders. In contrast, it may be that stress, in the form of loss, is associated with anxiety symptoms. Although epidemiological studies have the advantage of minimizing referral biases, they typically include relatively small numbers of children with any single disorder, and these are often relatively mild. As a result, it is also helpful to consider data from clinically referred samples of severe cases.

The considerable effort that has been made to examine associations between children's anxiety disorders and aspects of their family social environment, such as parenting, has yielded inconsistent results, whether from community- or clinic-based studies. Some research suggests that parental behaviors represent nonspecific correlates of psychopathology in children: they relate to many forms of dysfunction, including anxiety, mood, and behavior disorders, and are not specific to anxiety disorders (Wood *et al.*, 2003). Moreover, parenting behaviors may have indirect effects, through interactions with genetic influences or/and children's temperament (Lewis-Morrarty *et al.*, 2012), which complicates attempts to relate parenting behavior to children's anxiety.

Despite inconsistency in findings, interest in environmental influences persists for two reasons. First, as reviewed below, basic research demonstrates strong developmental plasticity in responses to threats in rodents and nonhuman primates (Gross & Hen, 2004). Such findings generate interest concerning whether, and how, adverse social experiences may shape children's responses to threats through changes in brain function. Second, from a clinical perspective, anxiety disorders are associated with traumatic experiences (Steinberg & Avenevoli, 2000; Pine & Cohen, 2002). Some children may develop PTSD, but others may develop an anxiety disorder. Anxiety's consistent association with trauma raises the possibility of an association across a range of mild-to-more-severe environmental adversity.

Some studies find associations between adverse life events and pediatric anxiety, with the overall pattern suggesting modest associations (Eley & Stevenson, 2000; Hankin & Abramson, 2001; Williamson *et al.*, 2005). Few studies have been longitudinal, and most have determined life events through retrospective recall, thus raising the possibility that life events represent correlates rather than causes of anxiety. However, one longitudinal study found that adverse life events during adolescence predicted risk for anxiety 4 years later, especially generalized anxiety disorder in females (Pine *et al.*, 2002). Finally, there may be particularly potent effects from stressors that

interact with a child's underlying vulnerability. For example, children with underlying anxiety have been reported to face particularly high risk for social anxiety disorder when exposed to stressful peer relationships, that is, bullying (Crawford & Manassis, 2011).

Stress reactivity

There is great variability in children's reactivity to stress, suggesting that underlying vulnerability may interact with stress exposure. Stress vulnerability has been indexed by physiological responses. For example, elevated heart rates after trauma have been linked to risk for PTSD (Kassam-Adams *et al.*, 2005). Similarly, there are associations reported among children's internalizing symptoms, children's physiologic response to a stressor, and marital conflict (Obradovic *et al.*, 2011). Reactions to various forms of stress have been examined, charted with many physiological parameters, including heart rate, cortisol level, skin conductance, and blinking rate. While some evidence of increased stress reactivity does emerge in anxiety, no clear and consistent strong associations emerge with specific forms of stress or particular physiological parameters.

Efforts have been made to quantify vulnerability to stress using questionnaires and personality inventories. A link has been reported between stress-reactivity tendencies and later anxiety disorders among children followed longitudinally (Pine *et al.*, 2001). Similarly, the Children's Anxiety Sensitivity Index (CASI), devised to assess the child's response to anxiety, may predict risk for anxiety symptoms. However, such measures may reflect current symptoms of anxiety disorders rather than vulnerability (Mannuzza *et al.*, 2002). Little data document associations between these or other stress vulnerability measures in currently healthy children and future anxiety disorders.

Medical conditions

Various medical conditions have been viewed as risk factors for anxiety disorders, operating during various phases of development. During the perinatal period, this includes overt neurological injury, febrile seizures, low birth weight, exposure to toxins, and minor neurological soft signs (Shaffer *et al.*, 1985; Breslau, 1995; Whitaker *et al.*, 1997; Breslau & Chilcoat, 2000; Breslau *et al.*, 2000; Vasa *et al.*, 2002). However, as is the case for other risk factors, relationships are neither strong nor consistent. Relative to behavior disorders, pediatric anxiety is less consistently associated with overt neurological injury and brain trauma (Gerring *et al.*, 2002). In fact, some forms of injury may even be protective (Vasa *et al.*, 2004). Like other risks, medical factors likely interact with children's underlying vulnerabilities to place them at risk for anxiety (Shaffer *et al.*, 1985).

Of all physiological factors associated with childhood anxiety disorders, the strongest evidence is for the role of respiratory dysregulation. Recurrent experiences that produce dyspnea incur risk for pediatric anxiety disorders (Slattery *et al.*, 2002; Goodwin *et al.*, 2003); Asthma, for one, confers risk for two specific anxiety states: separation anxiety disorder and panic

attacks. Similarly, cigarette smoking during adolescence, which has deleterious effects on respiratory function, also predicts future panic attacks but not social anxiety (Johnson *et al.*, 2000). The same is not generally the case for illicitly abused substances, which exhibit broader associations with anxiety (Rutter *et al.*, 2006). These findings are consistent with considerable research implicating respiratory dysfunction in childhood separation anxiety disorder and adult panic disorder.

Pathophysiology

Genetics

Research on familial aggregation has examined genetic transmission at the level of diagnostic concordance, that is, family and genetically informative studies. Other research examines concordance of intermediate phenotypes and associations with specific genes.

Family studies

Multiple studies, appearing in Table 60.2, have reported an association between parental psychopathology and childhood anxiety disorders. These so-called “top-down” studies evaluate offspring of parents with anxiety disorders. A handful of so-called “bottom-up” studies have ascertained parents of children with anxiety disorders.

A major question concerns the diagnostic specificity of transmission of anxiety disorders. Are they associated with parental anxiety disorders exclusively, or also with major depression (Middeldorp *et al.*, 2005)? The weight of the evidence from studies in Table 60.2 indicates that both parental anxiety and depression predispose children to develop anxiety disorders. Another question concerns the concordance between specific anxiety disorders in parents and offspring. Do anxiety disorders breed true? Here, the evidence is mixed. Some work supports specificity of concordance. For example, a specific, consistent association has been found between parental panic disorder and separation anxiety disorder in offspring. (Capps *et al.*, 1996; Biederman *et al.*, 2001; Biederman *et al.*, 2004). Moreover, separation anxiety disorder accompanied by respiratory dysregulation has a specific association with parental panic disorder (Roberson-Nay *et al.*, 2010), consistent with other data (Klein, 1993). At the same time, others find little transgenerational specificity (Biederman *et al.*, 2004).

Genetically informative designs

Attempts to quantify environmental and genetic components traditionally use twin and adoption studies. However, only twin studies have been conducted on pediatric anxiety disorders.

Twin studies with adults suggest that genetic factors account for approximately 40% of the risk for anxiety, with the remaining variance mostly attributed to nonshared environmental factors (Hettema *et al.*, 2001; Hettema *et al.*, 2005). Moreover, in adults, there is evidence of both unique and shared

liabilities across specific disorders. Thus, adult generalized anxiety disorder and major depressive disorder have been found to share an underlying genetic substrate, differing largely in contributions from nonshared environmental factors. Studies of depressive symptoms in adolescents report comparable associations, namely, that the same set of genes predispose to anxiety before puberty, and to depression after puberty (Silberg *et al.*, 1999; Silberg *et al.*, 2001). There is other evidence of disorder-specific genetic risk for a few features of adult anxiety disorders. For example, in adults, there appears to be distinct genetic risk for panic disorder, phobias, generalized anxiety disorder, and major depression (Hettema *et al.*, 2005). At the same time, other evidence suggests that all forms of adult anxiety result from a complex mix of genetic influences, including both disorder-specific, and disorder-unique, liability factors (Middeldorp *et al.*, 2005).

Early studies generated divergent estimates of heritability, related to methodological differences (Eley & Stevenson, 1999; Topolski *et al.*, 1999; Eley *et al.*, 2003; Eley *et al.*, 2004; Bolton *et al.*, 2006). However, recent approaches have begun to overcome methodological difficulties. The most extensive research has been with separation anxiety disorder. Eighteen cohorts have generated heritability estimates generally consistent with findings on adult anxiety disorders (Scaini *et al.*, 2012). Other work has examined the heritability of scale scores on broad-band scales (Lamb *et al.*, 2010) or of behavioral inhibition (Goldsmith & Lemery, 2000). For both, genetic factors account for about 30–40% of the variance, with nonshared environmental factors accounting for much of the remaining variance, as in adults. Novel findings also emerge from longitudinal studies of twins using brief anxiety-symptom rating scales. They suggest that the underlying genetic architecture of pediatric anxiety transforms with development, potentially reflecting time-sensitive activation, and suppression of specific genetic factors, potentially interacting with environmental risk (Kendler *et al.*, 2008).

Symptomatic expression may represent a downstream manifestation of genetically-based perturbations in neural function. The term “endophenotype” refers to the heritable component of a phenotype, believed to be more closely linked to neural function than the disorder itself (Gottesman & Gould, 2003). In the entire field of mental health, there is only weak support for a few possible endophenotypes. In pediatric anxiety disorders, three have received moderate support: behavioral inhibition, autonomic function (Grillon *et al.*, 1997; Merikangas *et al.*, 1999), and respiratory dysfunction (Battaglia *et al.*, 2009; Roberson-Nay *et al.*, 2010).

Molecular genetics

Perspectives on psychiatric genetics have advanced to the point where most mental disorders, including pediatric anxiety disorders, are viewed as so-called “complex disorders.” The complexity is related to the panoply of genetic and nongenetic factors, each making small contributions to the phenotype. One approach has attempted to link specific genetic polymorphisms

Table 60.2 Anxiety in children as a function of parental psychopathology.

Top-down studies		Odds ratio between parental psychopathology and anxiety disorders in offspring versus normal controls
Author	Parental diagnosis (N of offspring)	
Weissman <i>et al.</i> (1984)	MDD and PD (19) (mothers) MDD (23) (mothers)	10.4* 2.3

Parental diagnoses: MDD, OCD, AGO, PD, = major depression, obsessive compulsive disorder, agoraphobia, panic disorder.

Offspring diagnoses: OAD, GAD, SAD, AD = overanxious disorder, generalized anxiety, separation anxiety, anxiety disorder including PD, OCD, or social phobia.

T1, time one; T2, 2-year follow-up.

*95% confidence interval of odds ratio excludes 1.0 (i.e., statistically significant at $p \leq 0.05$)

to neural and cognitive dysfunction in anxiety disorders, but this has not generated consistent findings (Pine *et al.*, 2010). Some findings suggest that genetic perturbations predispose to psychopathology through their interaction with environmental risk (see Chapters 23–25). For example, adults with two specific alleles and high stress exposure are reported to be at relatively elevated risk for major depressive disorder (Caspi *et al.*, 2003). However, there is controversy about the robustness of these associations (reviewed elsewhere in this volume), and about approaches used for testing interactions with specific genes. A final set of studies has used other techniques with inconclusive results (McGrath *et al.*, 2012; Sakolsky *et al.*, 2012).

Psychobiology

Neural circuitry in animals

Advances in animal research have led to the view that differences in anxiety states reflect individual differences in neural function (Gross & Hen, 2004). Animal models have been useful because there is strong cross-species conservation in the brain circuitry of fear and anxiety states. Perhaps the best understood phenomena are learned fears, which can be modeled by the so-called “fear-conditioning” experiment, where an aversive stimulus, such as a shock or air-puff, is paired with a neutral stimulus, such as a light or tone. Figure 60.1 illustrates the format of the fear-conditioning experiment in a rodent.

Figure 60.1 This figure shows two specific behaviors that have been studied in animals and extended through brain imaging research to children. One of these behaviors involves fear conditioning, when a neutral stimulus acquires the capacity to evoke fear, and extinction, when subsequent learning allows the organism to no longer treat the conditioned stimulus as dangerous. The other behavior involves attention orienting, when a threat in the environment captures attention. Brain imaging research links fear conditioning to a brain circuit involving the amygdala and the ventro-medial portion of the prefrontal cortex (PFC). Similarly, studies of the amygdala and ventro-lateral PFC functions link clinical anxiety to perturbed attention to threat.

Following conditioning, the formerly neutral stimulus provokes fear, through changes in neural circuitry involving the amygdala, which is a bilateral collection of individual nuclei located within the brain's medial temporal lobes (LeDoux, 2000). Once fear is established, some individuals retain it, while others do not—the fear has become extinguished. The failure to extinguish might reflect the failure of an active neural process leading to a tendency to maintain anxiety. Consequently, there is considerable interest in the process of extinction, which is mediated by specific sectors of the frontal cortex (Quirk & Gehlert, 2003). This process is also illustrated in Figure 60.1, when the conditioned stimulus is repeatedly presented without the aversive stimulus.

Unlearned fears that develop without prior experience are regulated by distinct, but related, neural circuits from the circuits that regulate conditioning and extinction (Davis, 1998). Unlike learned fears, unlearned fears may not extinguish, suggestive of distinct neural circuitry. Much like work on extinction, research on unlearned fear may be particularly clinically relevant, because most clinical anxiety involves fear about circumstances that arise independent of previous learning.

Neural development and fear

Functioning of the mature fear circuit in rodents reflects long-term influences of the early life rearing environment. Much work in rodents shows that rearing effects occur during specific points in development. Interference with normal maternal care, specifically early in development, lowers the threshold for engaging the fear circuit (Meaney, 2001). Work in nonhuman primates demonstrates at least some comparable associations (Suomi, 2003), with some evidence of unique developmental effects (Amaral, 2002).

Human physiology and neural circuitry

The peripheral physiologic measure best understood in humans, in terms of neuroanatomical detail, is the startle reflex. At least in some circumstances, the same neural circuit involved in fear conditioning in rodents is thought to mediate augmentation of this reflex in humans. Individual differences in anxiety have been related to startle abnormalities in various samples, including in children and adult anxiety disorders (Grillon, 2002; Grillon & Baas, 2003), and in asymptomatic children of parents with an anxiety disorder (Grillon *et al.*, 1997, 1998) or major depression (Grillon *et al.*, 2005).

Despite cross-species parallels, reservations about clinical relevance remain. Overall, observed associations with clinical indices are marginal, at best, for either startle or skin conductance response (SCR) (Lissek *et al.*, 2005). Beyond measures related to conditioning, the most developed physiologic line of research has examined associations between respiratory dysregulation and panic disorder (Klein, 1993). Much like a well-lit room for a rodent, respiratory stimulants represent unlearned, fear-inducing, stimuli for air-breathing organisms, including humans. A wealth of studies suggests that

sensitivity to respiratory stimulants (such as carbon dioxide [CO_2]) identifies individuals with a diathesis for anxiety closely related to spontaneous panic attacks. Sensitivity to CO_2 has been found in children with separation anxiety disorder, but not social anxiety disorder, and especially in children with the combination of separation anxiety disorder and parental panic disorder (Roberson-Nay *et al.*, 2010). These associations tend to be found more consistently than with measures of startle or SCR. Nevertheless, even for such respiratory measures, the findings remain of minimal clinical significance at the current time.

Recent work in rodents suggests that the amygdala directly detects CO_2 and produces fear behaviors. In an experiment of nature in humans, the role of the amygdala in response to CO_2 was examined in three individuals with a very rare condition, the Urbach-Wiethe syndrome, which produces both specific bilateral amygdala lesions, and the inability to experience some types of normal fears. It was expected that, in the absence of a functioning amygdala, subjects would not experience fear when exposed to 35% CO_2 . Unexpectedly, all three responded with severe fear, approximating panic. Therefore, it appears that fear reactions to CO_2 are regulated by a circuit that does not encompass the amygdala. Such findings are consonant with the view that neural mechanisms, leading to panic disorder, differ from those in conditioned fears and phobias, and that panic attacks are not simply expressions of exaggerated fear. This topic has received much attention, primarily focused on research in adults, where panic disorder typically is expressed.

Human cognition and anxiety

Threats receive priority for cognitive processing, relative to neutral stimuli, as is reflected in several psychological processes, most consistently attention and memory. In animals, the effect can be studied using brain lesions or neurophysiologic recordings, and in humans using performance on laboratory paradigms. While a range of cognitive processes have been explored, the data most consistently link individual differences in attention to differences in anxiety (Pine *et al.*, 2009). Therefore, this area is selectively summarized.

In animals, threats have been shown to disrupt strategic control of attention or attention orienting (Davis & Whalen, 2001). Two procedures have been used most consistently in humans to probe threat-related effects on attention. In one procedure, the so-called emotional-Stroop test, increases in latency emerge when naming the colors of “threat” words compared to “neutral” words (Williams *et al.*, 1996). In the other procedure, the so-called “dot-probe test,” reaction time to a spatial probe is quantified depending on how close the probe is to “threat” words or pictures (Mogg & Bradley, 1998; Bar-Haim *et al.*, 2007). Both tests find relatively consistent associations with anxiety in children and adults. The circuitry mediating these behaviors has been mapped in humans and other mammals, as illustrated in Figure 60.1, adjacent to the schematic fear conditioning experiment. For attention, the figure displays the capacity of natural

threats, such as the snake in the figure, to capture attention. This circuitry is thought to be supported by multiple components, including a component in ventro-lateral prefrontal cortex (PFC) that becomes engaged very rapidly after a threat is encountered. Because this attention response can be deployed very rapidly, even outside of awareness, special techniques might be needed to change such attention responding. For example, novel work in this area uses computer-based cognitive training to reduce attention bias in healthy and anxious children and adults (Eldar *et al.*, 2012). Thus, research on attention in anxiety may one day become clinically relevant.

Imaging

Most brain imaging studies in anxious children rely on one of two imaging procedures: neuromorphometry, which measures brain structure, and functional magnetic resonance imaging (fMRI), which measures changes in blood flow in various brain regions, during various cognitive processes. Only a handful of imaging studies examine anxious children. While morphometry studies have demonstrated perturbations in amygdala volume as a function of anxiety in children and adults (Blackford & Pine, 2012), some studies find increased volume whereas others find decreased volume in anxious relative to nonanxious individuals. Other findings are similarly inconclusive.

Functional imaging studies have used fMRI in children with anxiety disorders, as well as related phenotypes, such as behavioral inhibition. Here, consistent findings emerge for the amygdala, expressed as increased response in anxiety relative to healthy individuals for various fear producing stimuli (Pine *et al.*, 2009), as well as in the PFC and striatum (Blackford & Pine, 2012). Thus, findings link perturbations in distributed neural circuits to individual differences in anxiety.

Given cross-species conservation of brain-behavior relationships for fear, there is interest in using fMRI to extend studies in animal models to children and adolescents in a way that is clinically relevant. This research, referred to as “translational” or “clinical” neuroscience, attempts to connect work in animals and humans, as illustrated in Figure 60.1. This figure shows two types of behaviors for which relevant circuitry has been mapped in animals, and for which brain imaging studies are now extending to children and adolescents.

One of these behaviors is shown for a rodent, in the top left-hand corner of the figure, illustrating the expression of fear conditioning. In humans, the circuitry of this process is depicted in the lower left-hand corner of the figure, in blue shading. This circuitry connects the amygdala to the ventro-medial portion of the PFC, as illustrated in the schematic depiction of the child in Figure 60.1. Understanding the relationship between fear expression and brain function has led to interest in the possibility of developing novel pharmacological, computer-based, or psychotherapeutic treatments that target specific circuitry, including the amygdala-PFC circuit involved in conditioning. However, this area is in its infancy, and means for achieving this clinical goal have not yet been defined.

Figure 60.1 also shows a second, potentially clinically relevant behavior. The figure depicts a boy, as he walks in a wooded area, appearing in the lower right corner of the figure, encountering a snake. The figure conveys that dangerous stimuli, such as snakes, capture the boy’s attention. As noted above, there has been considerable work mapping the brain circuitry of this attention capture. Like extinction, this behavior also involves a brain circuit connecting the amygdala and PFC. However, whereas extinction involves ventro-medial aspects of the PFC, the capture of attention by threats is thought to involve ventro-lateral aspects of the PFC. In Figure 60.1, this component of the PFC is illustrated in green, and conveys the role of this circuit in regulating attention capture. Much like work on ventro-medial PFC function, interest in ventro-lateral PFC function in anxiety also relates to the pursuit of novel treatments. However, this goal is complicated by the fact that changes in brain circuitry involve a huge number of neurons, whose extraordinary speed of function may prove difficult to capture through currently available techniques.

Treatment

Evidence of suffering experienced by children with anxiety disorders, coupled with findings of long-term effects on functioning, highlights the need for effective treatments. This summary is limited to replicated, large controlled studies that provide evidence of efficacy, and excludes claims of efficacy from case studies. However, the discussion of treatment, unlike other sections of this chapter, includes some observations from clinical experience. In this instance, reference to clinical experience is designed to inform about the use of treatments, which have been shown to be effective.

Although it is parents who seek help for their child, they are frequently unaware of multiple aspects of the child’s disorder and its functional ramifications. Therefore, regardless of treatment modality, therapists need to assist parents in understanding the child’s condition in all its aspects, as well as how treatment is expected to proceed.

The treatment of anxiety disorders is privileged insofar as several effective approaches, psychotherapeutic and psychopharmacological, have been documented. Many studies include multiple anxiety disorders, typically generalized anxiety disorder, separation anxiety disorder, and social phobia; only a few are restricted to one diagnosis. As a result, clinicians are on reasonably solid ground when extrapolating data on therapeutics to children with any of these anxiety disorders.

Some interventions, such as cognitive behavior therapy (CBT), were originally implemented in anxiety disorders based on a theoretical model of anxiety; others, such as selective serotonin reuptake inhibitor (SSRI) medications, followed from demonstrated efficacy in adults. However, for both, decisions on clinical utility ultimately rest on results of well-conducted randomized controlled trials. Independent of the results from such trials, there are national differences in attitudes

toward psychiatric treatment of children, which affect practice. Generally, psychopharmacology is widely accepted in the US, but not universally so, for treating children's psychiatric disorders including anxiety disorders. It is much less so in Europe. However, negative views of psychopharmacological treatment are not based on empirical data establishing the better efficacy or less extreme adverse consequences of one approach versus another, but more likely on beliefs about medication. For example, some individuals view the use of medication as stigmatizing or as defining a child as sick. Others have raised concerns about medications' harmful effects on development. Chapter 43 discusses these issues in depth. Regardless, while more research is needed on various aspects of medications, at the current time, data do not support such concerns with regard to pediatric anxiety disorders. Moreover, as reviewed below, the available data document additive effects with the use of medication and psychotherapy, over either alone, in anxious children. As a result, both treatments clearly have a role in the management of pediatric anxiety disorder.

Psychotherapy

CBT is the best-studied psychotherapy. It is based on various theoretical concerns. One of these concerns follows from the notion that distorted cognitions underlie anxiety symptoms. Consequently, a key aspect of CBT focuses on the child's thought processes, aiming to replace negative beliefs with realistic, neutral, thoughts. The goal is to enable children to abandon irrational thinking about their fears and develop more realistic evaluations.

A second concern relates to avoidance. When children are encouraged to confront their fears and no longer avoid them, they can learn to overcome their fears. Consequently, a second aspect of CBT focuses on reducing avoidance and facilitating children's exposure to feared situations.

Eventually, in virtually all treatments that adopt a CBT approach, a systematic program of gradual exposure to feared situations is implemented, typically using similar components. These may include psycho-education about anxiety, instructing the child to understand his condition, relaxation training, identifying the physical symptoms of one's anxiety, teaching of cognitive strategies for coping, and cognitive restructuring. These components are usually implemented early. Next, children are helped to undergo graded exposure during which they are expected to use their newly learned strategies while receiving self-reinforcement as well as encouragement from the therapist and parents. Of note, not all CBT treatments actively include the family's involvement. However, because parent involvement is important in most cases to facilitate the child's exposure to feared situations, active involvement of families is expected even for forms of CBT that do not explicitly stipulate family involvement. For example, it is difficult to appreciate how a child with severe separation anxiety can receive optimal therapeutic assistance without considerable parental involvement. Some children may have difficulty articulating their thoughts and

even their fears. In such situations, more effort will be deployed on systematic gradual exposure, to eliminate behavioral avoidance, than on self-monitoring of thought processes. Because a main source of anticipatory anxiety is due to the uncertainty of what may happen, it is helpful to involve anxious children in the process of selecting how to implement exposures to feared situations, so children are fully cognizant of what is expected of them (the "what if" worry, characteristic of anxious children, is thereby minimized).

A major positive feature of CBT is the availability of treatment manuals. These provide a useful guide for treating individual children. Moreover, treatment manuals allow comparisons across studies using different variants of CBT. Many studies have compared CBT to other conditions, most often a no-treatment or wait-list control. Because wait-list controls are inadequate to control for many nonspecific effects of CBT, a far more informative approach involves a comparison with an active attention control (psychotherapy without specific content). Very few studies have included attention controls.

A recent relatively large multisite study found that 12 weeks of intensive CBT was superior to a pill placebo, with marked improvement rates of 59.7% versus 23.7%, respectively (Walkup *et al.*, 2008). Problematically, pill placebo and psychotherapy contrasts cannot be blinded, nor equivalent in professional attention. As a result, in such designs, the true advantage of the psychotherapy cannot be confirmed, since one might assume a greater expectation of benefit to accrue in an unblinded psychotherapy context than in a blinded medication/pill placebo contrast.

Although specific phobias, separation, social, and generalized anxiety disorders all are anxiety disorders, they have different behavioral consequences; these are typically targeted by treatment tailoring. In this spirit, some treatments have been developed specifically for social anxiety. Social Effectiveness Therapy for Children (SET-C), one such treatment, is a clinic-based group psychotherapy for social anxiety, focused on the behavioral, rather than cognitive aspects of social anxiety. It provides the context of a social group, which is often anxiety provoking for those with social anxiety disorder, relying on *in vivo* exposure to feared social situations as a central treatment component. SET-C places particularly strong emphasis on behavioral exposure to enhance extinction, and to social skills training, rather than distorted thinking, which is more strongly emphasized in other studies of CBT.

Evidence shows that most youngsters who suffer from anxiety disorders are not referred for treatment. Various strategies have been used to reach such children; one is incorporated in schools to identify and treat unidentified children. For example, a school-based group intervention for socially anxious adolescents has been developed, utilizing principles of SET-C. This intervention, administered directly in high schools, has been shown to be effective, compared to a nonspecific control treatment (Masia-Warner *et al.*, 2007). Such school-based treatments have the great advantage of allowing for intervening

in the setting in which consequences of social anxiety are most deleterious. Other approaches capitalize on increased access that might be possible through computers and social media. For example, internet-delivered CBT has been developed (Khanna & Kendall, 2008). Evidence of efficacy for children with anxiety disorders has not yet been documented.

At this time, we do not know which components of effective treatments produce benefit. Moreover, from a clinical perspective, high rates of remission for a range of treatments, including placebo, suggest that there may be merit to postponing specific formal intervention for a couple of weeks, while monitoring the child's progress.

CBT has been examined for potential preventative effects. Some forms of prevention target children already affected with some relatively mild levels of anxiety or with behavioral inhibition, a potential precursor of more severe anxiety. In these studies, children receive CBT in attempts to prevent the development of full-blown anxiety disorders. Results suggest that CBT reduces anxiety symptoms in such children (Rapee *et al.*, 2005). However, since the children already have some levels of anxiety symptoms, the interventions only apply to an affected, select group of children.

Pharmacotherapy

SSRIs have extensive documentation of safety and efficacy in adult anxiety disorders (specific phobias are exceptions). From a number of controlled studies, the consensus is that SSRIs are highly effective in a variety of pediatric anxiety disorders. The large multisite study, noted earlier, of CBT, sertraline (up to 200 mg/day), combined CBT-sertraline, or placebo, found significant benefit for each mono-therapy over placebo (improvement rates: CBT, 59.7%; sertraline, 54.9%; placebo, 23.7%), and significant superiority for combined treatment (80.7%) over each mono-therapy (Walkup *et al.*, 2008). The contrast between sertraline and placebo in this study is fully blinded, but not the other contrasts, complicating straightforward interpretation of treatment differences. Other findings show efficacy of 6–8 weeks of fluoxetine, paroxetine, sertraline, or fluvoxamine over placebo, in anxious children.

The SSRIs have similar side effect profiles, the most troublesome being behavioral disinhibition (the child becomes ornery, impulsive, or oppositional). Therefore, it seems wise to initiate treatment with a short acting SSRI, and possibly switch to a long-acting formulation, if indicated, such as when compliance is deficient or when the clinician has concerns about potential withdrawal effects. The superiority of combined SSRI and CBT treatment over either mono-therapy fosters questions about the clinical scenarios for which combined treatment is likely to be optimal. Because studies have not addressed this question, we rely on clinical experience. For example, based on clinical observations, there are children who, with behavioral treatment, are able to enter situations they avoided before treatment, but they do so under duress, and still feel anxious. In such instances, addition of an SSRI often reduces residual anxiety. Similarly,

in other scenarios, children may be extremely anxious, to the point where they cannot even begin to initiate exposure therapy. Here, initiation of an SSRI may reduce the child's anxiety in the feared situations to the point where he/she can begin systematic exposure. Based on clinical observations, SSRIs are especially efficacious for anxiety experienced while in the feared situations, but less so for anticipatory anxiety. Consequently, even with a good response to an SSRI, children may retain significant anticipatory anxiety, but not so high so as to preclude exposure, which, in turn, facilitates extinction of anticipatory anxiety. Some clinicians hold that it is advisable to start with behavioral treatment, since it quickly becomes apparent whether it is likely to be helpful, followed by medication, when indicated, for maximal improvement. Thus, based on the literature, one should not settle for less than an excellent response until combined treatment has been attempted.

Summary

Multiple findings demonstrate the clinical importance of child and adolescent anxiety disorders. These include their relatively high prevalence; their associated functional limitations; the fact that they put children at risk for later depression; and their moderately significant continuity with anxiety disorders in adulthood. Epidemiological data generate divergent prevalence rates, with an overall 5-to-10% prevalence in the general population, with girls being overrepresented. Long-term stability has been found for anxiety disorders as a group, but limited evidence of differential outcomes has emerged for particular anxiety disorders. Importantly, childhood anxiety disorders generally have not been found to predict adult psychopathology other than anxiety and depression.

Identification of antecedents of childhood anxiety disorders would facilitate attempts to help children at risk and prevent the development of full-blown anxiety disorders. Early inhibited temperament is one of the few replicated antecedents, acting as a moderate risk factor, particularly for social anxiety disorder. A modest influence for genetic transmission has been found. Nonshared environmental factors appear to play a relatively greater role, but their nature and mechanism of action remain poorly understood. As a result, there is little promise in the targeting of particular environmental factors for prevention or clinical management of childhood anxiety disorders.

Models of brain circuits that regulate fear in animals are being investigated in children. Early studies demonstrate some cross-species similarities. However, it is difficult to disentangle cause and effect, since most imaging studies acquire data at one time point. At this time, the best documented biological feature is for separation anxiety disorder, consisting of respiratory dysregulation, as indexed by hypersensitivity to breathing CO₂ enriched air, which induces perturbations that appear similar to those found in adults with panic disorder.

Treatment of anxiety disorders encompasses psychotherapeutic and psychopharmacological interventions, specifically CBT, behavioral therapy, and SSRIs. Treatment studies of anxious children, with few exceptions, have included multiple anxiety disorders, except for studies of children with social anxiety, exclusively.

CHAPTER 61

Obsessive compulsive disorder

Judith L. Rapoport¹ and Philip Shaw²

¹ Child Psychiatry Branch, National Institute of Mental Health, Bethesda, MD, USA

² Social and Behavioral Research Branch, and Head, Neurobehavioral Clinical Research Section, National Human Genome Research Institute, Bethesda, MD, USA

Definition: the concept and current issues

Obsessive-compulsive disorder (OCD) was once considered rare in childhood, but recent advances in diagnosis and treatment have led to the recognition that the disorder is a common cause of distress for children and adolescents. OCD is characterized by the presence of obsessions (unwanted, repetitive, or intrusive thoughts) and compulsions (unnecessary repetitive behaviors or mental activities). Because the obsessive-compulsive thoughts and rituals are usually recognized by the child as nonsensical, they are often kept hidden for as long as possible—from both parents and practitioners. This secrecy may have contributed to the fact that until the 1980s OCD was unfamiliar to most child psychiatrists, even though classic descriptions of the disorder featured cases with childhood presentation (Janet, 1903). The recognition that OCD was more common in adults than previously believed, and retrospective reports that one-half to one-third of adult subjects had their onset in childhood or adolescence, focused the attention of the child psychiatric community on this chronic and often disabling disorder (Karno *et al.*, 1988; Karno & Golding, 1991).

Until the mid-19th century, obsessive-compulsive phenomena were considered to be a variant of insanity. However, as the disorder was better defined, it came into focus as one of the neuroses. The descriptions of repetitive unwanted thoughts or rituals, often characterized by magical thinking and usually kept private by the sufferer, were relatively constant observations in those early reports. Debate about core deficits and the relative importance of volitional intellectual and emotional impairments (all of which are in some way abnormal in OCD) have flourished for over 100 years (Berrios, 1989).

Freud (1906, 1958) speculated about the similarity between obsessive-compulsive phenomena, children's games, and religious rites. Although psychoanalytic theory is empirically unproved and has not been shown to be effective in the treatment of OCD, the broad questions raised by Freud about continuity and discontinuity within individual development

and OCD, as well as with regard to secular and religious rituals, and cross-cultural studies linking cleanliness and “purity” remain fascinating issues. In addition, the association between certain neurological disorders, such as Tourette's disorder (see Chapter 56), and OCD, supported by current imaging research, has led to possible localization of brain circuits mediating obsessive-compulsive behaviors as well as mechanisms for behavioral encoding. Over the past decade, interest in these general questions, as well as the possibility of unique pediatric subgroups of OCD, has generated a wealth of clinical and translational research (Apter *et al.*, 1996; Fitzgerald *et al.*, 1999; Graybiel & Rauch, 2000a). Key issues which appear throughout this chapter are the degree to which at least some cases with childhood onset represent a distinct subtype (e.g., patients with Tourette's/tics and/or patients with a possible infectious trigger or pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections, PANDAS), the extent to which there is continuity with normal development, as well as the relationship between OCD and several other disorders now seen as part of an OCD spectrum such as body dysmorphic disorder or tricotillomania. The placement of this chapter within the emotional disorders remains warranted because of the comorbidity and familiarity of mood and anxiety disorders in OCD patients (Bienvenu *et al.*, 2012).

Epidemiology

Epidemiological studies provide a lifetime prevalence of around 1.9–3.3% (Karno *et al.*, 1988; Karno & Golding, 1991)—see Table 61.1. Using the Diagnostic Interview Schedule (DIS), a structured interview designed for lay interviewers, lifetime prevalence rates without DSM-III exclusions ranged from 1.9% to 3.3% across sites. Even with DSM-III exclusions, the rates were 1.2–2.4%. These rates were 25–60 times greater than had been estimated on the basis of clinical populations. The mean age of onset across the sites ranged from 20 to 25 years with 50%

Table 61.1 Community studies of OCD prevalence in children and adolescents.

Study	Sample	Ascertainment and evaluation	Prevalence (%)
Flament <i>et al.</i> (1988)	5596 students grades 9–12 (United States)	Initial screening with Leyton, epidemiological version; 356 screen-positive students then evaluated using semistructured interview by clinicians	1.0 and 1.9 (wt. current and lifetime, respectively)
Zohar <i>et al.</i> (1992)	562 consecutive army recruits, ages 16–17 yrs (Israel)	Short semistructured interview by a child psychiatrist	3.6 (point)
Reinherz <i>et al.</i> (1993)	384 mostly 18-yr-olds (United States)	Structured interview by trained interviewers with research or clinical experience	1.3, 1.3, 2.1 (1-mo, 6-mo, and lifetime, respectively)
Lewinsohn <i>et al.</i> (1993)	1710 14–18-yr-olds (United States)	Semistructured interview mostly by trained, clinically experienced interviewers	0.06, 0.53 (current and lifetime, respectively)
Valleni-Basile <i>et al.</i> (1994)	3283 (mostly) 12–15-yr-olds (United States)	3283 screened; 488 mother–child pairs then given semistructured interview by psychiatric nurses	2.95 (wt. current)
Douglass <i>et al.</i> (1995)	930 18-yr-olds from a birth cohort followed since birth (New Zealand)	Structured interview by trained mental health interviewers	4.0 (1 yr)
Apter <i>et al.</i> (1996)	861 consecutive army recruits, ages 16–17 (Israel)	Initial screening by an OCD self-report questionnaire followed by a structured interview by a child psychiatrist	2.3 (lifetime)
Wittchen <i>et al.</i> (1998)	3021 14–24-yr olds (Germany)	Semistructured interview by clinical interviewers and trained professional health research interviewers	0.6 and 0.7 (1 yr and lifetime, respectively)
Rapoport <i>et al.</i> (2000)	NIMH MECA four-site sample of caretaker–child dyads of 1285 9–17-yr-olds (United States)	Structured interview by trained interviewers	0.3, 2.5, 2.7 (parent report, child report, and total, respectively)

Note: wt. = weighted to reflect sampling design

developing symptoms in childhood or adolescence (Karno & Golding, 1991), providing further support for the retrospective accounts of the frequent pediatric onset of this disorder (Black, 1974). More recent cross-cultural studies with adults have been supportive of similar rates of between 1.9 and 2.5 percent prevalence across widely differing cultures (Horwath & Weissman, 2000). Higher rates are found using DSM-IV than with ICD-10, with only 64% agreement between the two systems (Andrews *et al.*, 1999). As about a half of adult patients report onset after adolescence or childhood, the similar rates for adult and child populations suggest that some pediatric patients must remit. This apparent discrepancy from the chronic nature of most pediatric OCD studied clinically has not been resolved (see discussion later), but may reflect in part that adult cases are typically identified using only one informant, whereas childhood cases are frequently diagnosed on the basis of two informants (the child and parent).

Epidemiological studies of OCD focusing on children and adolescents (see review by Zohar, 1999) and one recent additional study examined the results of a large four-site community survey in the United States (the National Institute of Mental Health [NIMH] Methods for the Epidemiology of Child and Adolescent Mental Disorders [MECA] Study) (Rapoport *et al.*, 2000). The lifetime prevalence across eight studies (from these two articles combined) indicates relative consistency with a

lifetime prevalence from 0.7% to 2.9%. Males have an earlier onset than females, contributing to a striking preponderance of males in most pediatric samples (Geller *et al.*, 1998). The variance in prevalence rates is likely to reflect differences in study design, particularly whether clinicians or nonclinicians conducted interviews. Additionally, prevalence estimates may also be sensitive to the diagnostic tools employed. Structured interviews in particular may yield false positives when given to children who are apt to misinterpret the questions (Breslau, 1987).

There is increasing reliance on standardized interviews and rating scales for both the study and clinical management of OCD. The most commonly used tools, the Diagnostic Interview for Children and Adolescents (Herjanic & Campbell, 1977; Herjanic & Reich, 1982) and the Schedule for Affective Disorder and Schizophrenia for School-Age Children (Kaufman *et al.*, 1997), have sections on OCD. In addition, there are several rating scales in general use, including the child version of the Leyton Obsessional Inventory (Berg *et al.*, 1989) and the Yale–Brown Obsessive Compulsive Scale (Y-BOCS) (Goodman *et al.*, 1989a,b) and a Children's Y-BOCS (CY-BOCS) adapted for 5–8-year-olds (Scahill *et al.*, 1997). Sensory phenomena such as getting things “just right” have been a valid and reliable auxiliary measure for OCD using the Sao Paulo Sensory Phenomena Scale (Rosario *et al.*, 2009).

Diagnostic issues

Continuity with normal development

The boundaries of diagnosis are complex in any disorder, and this is clearly the case with OCD. Individual “habits” that are typical of OCD are extremely common across populations. For example, in one Israeli study, only 18% of the sample endorsed no obsessive-compulsive symptoms at all, while a longitudinal population study found 21–25% of children and adults endorsed specific obsessions or compulsions (Fullana *et al.*, 2009). Moreover, many ritualistic and “magical” behaviors are part of normal development (Leonard, 1989). As is the case with many disorders, family genetic studies seem to indicate that heritability of obsessive-compulsive symptoms may extend across the entire range of severity, and similarly twin studies support the model of OCD as the extreme of a continuously distributed trait with biological continuity between normal and abnormal behaviors (Jonnal *et al.*, 2000). However, there is evidence from a pediatric sample that symptom levels below the level needed for a categorical diagnosis of OCD predict later onset OCD, and are associated with help seeking for other mental disorders, particularly depression (Berg *et al.*, 1989; Fullana *et al.*, 2009).

The importance of informant history

Secrecy appears to be a hallmark of childhood onset OCD. The children recognize that their symptoms are nonsensical and are embarrassed by them, so they go to great lengths to hide them. Hand-washing might be disguised as more frequent voiding and rituals are carried out in private, so that children are often symptomatic for months before their parents are aware of a problem. Teachers and peers typically are aware only for cases with greater severity. As with Tourette’s disorder, children may expend effort controlling their behaviors in public and “let go” when at home. This partial voluntary control of symptoms often baffles and angers parents. Because of the variable degree and timing of control of symptoms, the nature of the informant has particularly important influence on recognition and diagnosis of OCD. As shown for the MECA data (Rapoport *et al.*, 2000), only 0.3% were identified by parents while 2.5% were identified through self-report from the child, with only one overlapping case.

Issues with DSM-5 diagnosis

OCD is defined in both ICD-10 and DSM-5 as repetitive intrusive thoughts and/or rituals that are unwanted and which interfere significantly with function or cause marked distress. The severity criteria avoid confusion of OCD with many childhood habits that are part of normal development. Both the content and relative insight into the unreasonableness of the thoughts/behaviors differentiate OCD from other disorders.

While clinical experience suggests that the adult criteria can be applied to childhood cases, there are several important caveats. Both DSM-5 and ICD-10 state that compulsions are designed to neutralize or prevent some dreaded event or according to rules that must be applied rigidly. The concept of “rules applied rigidly” is particularly useful for childhood OCD. While some children may not be willing or able to verbalize their obsessive thoughts, long-term contact has demonstrated that about 40% of children do not in fact have obsessive thoughts; they steadfastly report the presence of only compulsive rituals (dictated by rigid rules) accompanied by a vague sense of discomfort if the rituals are not carried out (Swedo *et al.*, 1989). At least a third of pediatric patients report that certain stimuli trigger their rituals and that avoidance of the trigger “protects” them from the obsessive-compulsive symptoms (Karno *et al.*, 1988). The degree of insight needed for the diagnosis is also in dispute as some patients, at least some of the time, “believe” their obsessive thoughts. DSM-5 diagnostic criteria now includes a subtype coding for the “belief” in the necessity for these thoughts/behaviors.

Due to the exclusion of either false positives or milder cases, rates of OCD tended to be lower with DSM-IV than earlier versions of the DSM, with a 12-month prevalence rate of 0.6% being reported in a recent study (Crino *et al.*, 2005). Estimates of lifetime prevalence appear to be less affected by the changes in diagnostic criteria (Angst *et al.*, 2004; Swedo *et al.*, 2004). There are several important differences between the ICD-10 and DSM-5 criteria, such as whether exclusions are made based on comorbid psychotic disorders, such as schizophrenia. DSM-5 allows patients to receive a diagnosis of OCD even in the presence of schizophrenias (American Psychiatric Association, 1994) in light of convincing evidence of coexistence with schizophrenia (Byerly *et al.*, 2005; Poyurovsky & Koran, 2005).

Obsessive compulsive spectrum disorders

The longstanding question of the importance of other disorders involving over focused interfering behaviors termed “obsessive compulsive spectrum disorders,” and their relationship to OCD and to anxiety disorders, has led to an important reconceptualization of these disorders and a new umbrella category in DSM-5: obsessive-compulsive and related disorders. This grouping does not affect “caseness” but indicates that the OC spectrum disorders appear to be related. Spectrum disorders include body dysmorphic disorder, trichotillomania (hair pulling disorder), excoriation (skin picking), all of interest for pediatric populations, and hoarding disorder. The phenomenological similarities are often striking. For example, similar to OCD, body dysmorphic disorder and skin picking are characterized by over focused ideation and anxiety arousing concerns. Some of these disorders, for example, hoarding disorder, differ not only in content but also in the perceived ego-syntonic nature of the behaviors. The diagnosis of OCD is only given if

symptoms are not accounted for by these spectrum disorders. The relationship between OCD and these other disorders is complex. A neurobiological overlap with OCD is suggested by the increased rate of subclinical OCD features in relatives of those with spectrum disorder (Bienvenu *et al.*, 2000) and clinical comorbidity and familiarity of these spectrum disorders for OCD probands (Bienvenu *et al.*, 2012). The majority of spectrum disorder patients do *not* have comorbid OCD (Phillips *et al.*, 2010), and body dysmorphic disorder is only comorbid with OCD in about one-third of patients, and their insight is more limited. Hoarding disorder, a new diagnosis for DSM-5, is only comorbid with OCD in 20% of cases. The extent to which hoarding is a clinical problem in childhood is unclear but hoarding is most probably of greater interest for adults (Mataix-Cols *et al.*, 2012). There are also several studies which have suggested some efficacy for serotonin reuptake inhibiting drugs in the treatment of these disorders (Keuthen *et al.*, 2005; Saxena *et al.*, 2007), although there are notable negative treatment trials (Karno *et al.*, 1988; Christenson *et al.*, 1991; Hollander & Wong, 1995; Hollander, 1996; Hollander *et al.*, 2003). We will consider later the overlap between the neural substrates of OCD and the spectrum disorders.

Children with disorders that are less obviously related to OCD, such as autism spectrum disorders (ASDs), frequently exhibit a compulsive need for sameness but lack other features such as ego-dystonicity (the individual's sense that the content of his symptoms are alien and unlike his normal self). Disorders such as anorexia nervosa, pyromania, pathological gambling disorder, and substance abuse disorder overlap with OCD principally in that their symptoms involve overfocused ideation but are neither comorbid for OCD probands, nor is there increase in their families (Bienvenu *et al.*, 2012). There continues to be debate about classification of OCD as an anxiety disorder. However, depression and anxiety are major comorbidities with OCD, and there is evidence from family studies that OCD segregates with anxiety and mood disorders (Hanna *et al.*, 2011; Bienvenu *et al.*, 2012). The placement of OCD and related disorders as a separate category within anxiety disorders in DSM-5 may be a sensible compromise for the present.

Obsessive-compulsive personality disorder (OCPD) is defined by preoccupation with orderliness, perfectionism, and mental control at the expense of flexibility, openness, and efficiency. Generally these behaviors are not seen as ego dystonic in OCPD, but in practice the two disorders can be confused. OCPD has not been studied in pediatric populations but developmental studies would be of great interest.

Unique childhood onset subtypes

This leads to a related question as to whether OCD with very early onset represents an important subtype of the disorder or possibly a different disorder altogether. There is some evidence that at the very least, early age of onset represents a more

familial form of the disorder, particularly for pediatric cases with ordering compulsions (Leckman *et al.*, 2009). In one study, no patient with adult onset of OCD had a first-degree relative with OCD (Nestadt *et al.*, 2000). Additionally, very early onset OCD is more frequently associated with tics and/or Tourette's disorder (Grados *et al.*, 2001; Chabane *et al.*, 2004). Moreover, family studies have found that tic disorders are more likely to occur in patients who have relatives with OCD than in patients who lack a familial loading for OCD (Pauls *et al.*, 1995). This is partially addressed by the addition in DSM-5 of a tic-related subtype specifier for OCD (American Psychiatric Association, 2013).

The postulation of a postinfectious subgroup of pediatric OCD came about as a result of early reports of the association of OCD with Sydenham's chorea (Osler, 1894; Freeman *et al.*, 1965). This supported converging evidence of basal ganglia involvement in the etiology and/or maintenance of OCD (Wise & Rapoport, 1989). One example of a postinfectious subgroup has been identified by research at the NIMH, which identified a group of pediatric patients in whom symptom onset or exacerbations are triggered by streptococcal infections; the subgroup is identified by the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) (Swedo *et al.*, 2004). This group of patients appears to have an unusually abrupt onset of symptoms, typically has an abnormal neurologic examination during exacerbations (particularly tic or choreiform movements, which are discussed in Chapter 56), comorbidities including separation anxiety and attention deficit hyperactivity disorder (ADHD) like symptoms, and tends to have a better outcome. The disorder is thought to arise through a process of molecular mimicry, with the group A β -hemolytic streptococcus (*Streptococcus pyogenes*) (GABHS) evoking antibodies that are capable of cross-reacting with specific areas of the human brain (e.g., the basal ganglia) to produce neuropsychiatric and behavioral symptoms. Moreover, the group showed response to immunotherapy (Perlmutter *et al.*, 1999a). However, there remains controversy around the diagnosis, particularly in view of some studies failing to detect elevated levels of autoantibodies in those otherwise meeting criteria for PANDAS (Singer *et al.*, 2005). More recently there has been a proposal to broaden the category to pediatric acute onset neuropsychiatric syndrome or PANS (Swedo *et al.*, 2012) or similarly childhood acute neuropsychiatric symptoms or CANS (Singer *et al.*, 2012), which is defined by abrupt onset rather than etiology and must include OCD or food restriction and other concurrent psychiatric symptoms.

Clinical presentation

Childhood onset OCD has been documented as early as age 2 but more typically begins later in childhood or early adolescence (American Psychiatric Association, 1994). In general, the symptoms of OCD in children mirror those in adult patients and are summarized in Table 61.2. Thus, obsessions on the

Table 61.2 Presenting symptoms in 70 consecutive children and adolescents with primary obsessive compulsive disorder.

Reported symptoms at initial interview	N	%
Obsessions		
Concerns with dirt, germs, and environmental toxins	28	40
Something terrible happening (e.g., death of loved one)	17	24
Symmetry, order, or exactness	12	17
Scrupulosity (religious obsessions)	9	13
Concern or disgust with bodily waste or secretions	6	8
Lucky or unlucky numbers	6	8
Forbidden, aggressive, or perverse sexual thoughts, images, or impulses	3	4
Fear of harming others or self	3	4
Concern with household items	2	3
Intrusive nonsense sounds, words, or music	1	1
Compulsions		
Excessive or ritualized hand-washing, showering, bathing, or grooming	60	85
Repeating rituals (e.g., going in and out of the door)	36	51
Checking (e.g., doors, locks, stoves)	32	46
Miscellaneous rituals (e.g., writing, moving, speaking)	18	26
Rituals to remove contact with contaminants	16	23
Touching	14	20
Measures to prevent harm to self or others	11	16
Ordering or arranging	12	17
Counting	13	18
Hoarding/collecting rituals	8	11
Rituals of cleaning household or inanimate objects	4	6

As multiple obsessions and compulsions are possible, the total thus exceeds 70.

Source: Based on Swedo *et al.* (1989).

themes of contamination, danger to self or others (such as fears that parents will be harmed), symmetry or moral issues are common; typical compulsions include washing, checking, and repeating—particularly until the child experiences a feeling of “getting it just right” (Despert, 1955; Thomsen, 1991; Masi *et al.*, 2005). Most children have a combination of obsessions and rituals, and pure obsessives are rare compared with the more frequent pure ritualizers. Children with an early age at onset (below age 6) usually begin their rituals or obsessions in an easily recognizable fashion, such as excessive hand-washing or ritualized checking and repeating. In some cases, however, the clinical presentation is altered by the child’s developmental immaturity. For example, one 6-year-old boy, who was compelled to draw zeros repetitively, had started at age 3 to circle manhole covers on city streets. His tantrums when the circling was interrupted, his subjective distress during the behavior, and his lack of other psychosocial abnormalities or disorders (such as autism or pervasive developmental disorder) led to the diagnosis of OCD. Another child, who presented at age 7 with clinically significant checking compulsions, had been evaluated previously at 3 years of age when he developed a “compulsion” to walk only on the edges of the floor tiles. Cleaning rituals in children too young to reach the water faucet can present as excessive hand-wiping or licking.

Approximately one-third of pediatric patients report that certain stimuli trigger their rituals and that avoidance of the trigger “protects” them from the obsessive-compulsive symptoms (Swedo *et al.*, 1989). These phenomena have been viewed from an ethological perspective, with the compulsions conceptualized as “fixed action patterns” released by key environmental stimuli (Modell *et al.*, 1989; Wise & Rapoport, 1989). These triggers are of particular interest for treatment as they often determine the key approach during behavioral desensitization, namely, exposure with response prevention (see below).

Course and natural history

Epidemiological studies indicate that over 50% of adults with OCD report that their symptoms started during childhood or adolescence, with males generally having earlier onset than females (Rasmussen & Tsuang, 1984). A single epidemiological study of OCD in a group of 18-year-olds suggested that past depression and substance abuse were predictive of onset of OCD (Douglass *et al.*, 1995). There may also be a prodromal phase: parents of nearly half of the NIMH sample revealed that their children had displayed “micro episodes of OCD” years before developing full-blown symptoms. During these episodes, excessive rigidity and repetitive rituals (e.g., wearing the same clothes for a month, refusal to take a different path through the house) were a source of concern, albeit briefly.

A prospective epidemiological survey of 976 children, initially assessed between the ages of 1 and 10 years and then 8, 10, and 15 years later, delineated predictors of OCD symptoms (Peterson *et al.*, 2001). In prospective analyses, tics in childhood and early adolescence predicted an increase in OCD symptoms in late adolescence and early adulthood, whereas ADHD symptoms in adolescence predicted more OCD symptoms in early adulthood.

The clinical course of the disorder indicates some developmental influence on symptoms over time. In a clinic sample, this sensitivity to developmental stage was found first in symptom profile, with the presenting obsessions and compulsions changing over time in 90% of the NIMH pediatric patients (Rettew *et al.*, 1992). Most children began with a single obsession or compulsion and continued with this for months to years, and then gradually acquired different obsessions or rituals. Although the primary symptom would change (e.g., from counting to washing and then checking), some earlier symptoms often remained problematic, although to a lesser degree. The nature of the compulsive rituals also changed over time. A study of adolescents demonstrated that counting and symmetry were most prominent during grade school years, but were replaced by washing rituals during early and midadolescence (Maina *et al.*, 1999).

The outcome of OCD may also have a similar relationship to developmental stage. In their longitudinal epidemiological study of tics, OCD, and ADHD described above, Peterson and

colleagues found in prospective analyses that both younger and older adolescents with OCD were more likely to develop depressive and ADHD symptoms. Early adolescents with OCD, however, were especially likely to develop more anxiety and simple phobias in later adolescence. Epidemiological studies of adults suggest that spontaneous remissions occur in as many as one-third of patients (Karno & Golding, 1990). A recent prospective study of 591 adult subjects assessed patients at six time-points between age 20 and 40 (Angst *et al.*, 2004). While OCD was chronic in 60% of the cases, there was considerable improvement over time, even in those who continued to meet diagnostic criteria. It is often argued that pediatric cases will have a more chronic course, and a recent meta-analysis of studies based on sixteen independent samples (521 OCD participants) followed for a mean of 11.2 years indicated earlier age of onset to be a poor prognosis factor, along with comorbid psychiatric illness and poor initial treatment response (Stewart *et al.*, 2004). Overall, there was a 41% persistence for full and 60% for full or subthreshold OCD. A small study in which 45 of 62 pediatric OCD cases were recontacted a mean of 9 years later in early adulthood found 44% remitted in agreement with earlier studies (Bloch *et al.*, 2009). Poorer outcome was associated with absence of tics, more severe baseline symptoms, and female gender, as well as poor visuospatial and fine motor skills (Bloch *et al.*, 2009, 2011). A second clinic-based study found a similar 41% persistence rate of OCD in a group of children followed up over a mean of 5 years (Micali *et al.*, 2010). The pathways determining clinical outcome are complex, and any one single developmental variable, such as age of onset, is likely to account for only a modest amount of the overall variance in final outcome. OCD patients with comorbid tics or Tourette's have a waxing and waning course (Bloch *et al.*, 2006). In patients with comorbid Tourette's and OCD, tics generally start to improve around age 10, while the obsessive-compulsive symptoms typically continue for several more years. PANDAS are also characterized as relapsing/remitting in relation to streptococcal infection (Leonard *et al.*, 1999).

Associated disorders

Both epidemiological (Karno & Golding, 1991) and clinical (LaSalle *et al.*, 2004) studies indicate broad and complex comorbidity for OCD, similar to that seen for other major Axis I disorders. The patterns of comorbidity among childhood onset cases are generally comparable to those for adult samples, but with tic disorders and specific developmental disorders appearing more frequently in the pediatric populations. In the NIMH sample, only 25% of the pediatric subjects had OCD as a single diagnosis (Swedo *et al.*, 1989). Tic disorders (30%), major depression (26%), and specific developmental disabilities (17%) were the most common comorbidities, and there were also high rates of simple phobias (17%), overanxious disorder (16%), adjustment disorder (11%), attention deficit

disorder (10%), conduct disorder (7%), separation anxiety disorder (7%), and enuresis/encopresis (4%). While our own experience with comorbid bipolar disorder is limited, other groups find increased bipolar comorbidity in severely affected pediatric OCD cases (Masi *et al.*, 2004). This broad comorbidity remains to be explained (for this and other disorders) and is not accounted for by any of the etiological models discussed later. Obsessive Compulsive Personality Disorder rates are elevated in adults with OCD (25–32%); however, comorbidity of OCPD with other psychiatric disorders is quite broad, with particularly high rates for Major Depressive Disorder (see review in Phillips *et al.* (2010)).

Case illustrations

Case 1

A 14-year-old boy, whose symptoms had begun gradually, recalls at a very early age having to wash his hands repetitively. He was unable to associate an obsessive thought with this ritual, but he felt compelled to perform it. By age 6, he had developed an obsessive fear of tornadoes. He would repeatedly check the sky for clouds, listen to all weather reports, and query his mother about approaching storms. The tornado obsession faded over time and was replaced by a generalized fear of harm coming to himself or his family. He responded with extensive rituals to protect himself and his family. Particularly at times of separating, such as bedtime or leaving for school, the patient would be compelled to repeat actions perfectly or to check repetitively. When asked how many times he would have to repeat an action, he replied, "It depends. The number isn't always the same, I just have to do it right." When asked how he knew when it was right, he said, "I don't know, it just feels right." As the patient entered puberty, he became obsessed with acquired immunodeficiency syndrome (AIDS) and was convinced he would acquire it through his mouth. He began spitting in an effort to cleanse his mouth and would spit every 15–20 s. In addition, he began extensive washing rituals. Despite these cleansing and washing compulsions, his personal appearance was slovenly and dirty. He never tied his shoelaces because they had touched the ground and were "contaminated"; if he tied them, his hands would be "dirty" and he would have to wash until they were "clean" again. Remarkably, although his family was aware that "something had been wrong for a long time," most of the content of his obsessions was kept secret. This case illustrates the contamination concerns common to adolescents, as well as the variety and evolution of obsessive-compulsive symptoms during development.

Case 2

A 16-year-old girl had symptoms that began abruptly, shortly after the onset of menses. She called herself "a prisoner of my own mind." Her obsessions centered around a fear of harm to her parents. She was plagued by recurrent thoughts of her

mother dying in a car accident, her father being killed by an intruder, or both her parents dying of burns received in a house fire. Always a light sleeper, she began to get up during the night to check. She spent hours checking that the doors were locked, that the coffee pot was unplugged, and that the family dog was safely ensconced in the garage. Despite her obsessions about fire, however, she did not check the smoke detector, an excellent example of the irrationality of this superficially rational disorder. This patient involved her family in her rituals. Her mother made a checklist that the daughter carried to school, and both parents had to check the 24 items on the list, signing that they had done so. At night she would wake her father to help her check. The family involvement was so profound that behavioral treatment could only take place after a period of family counseling in which the parents were helped to separate from their daughter's illness.

The differential diagnosis: distinguishing OCD from other disorders

The broad comorbidity of OCD and an array of associated features make the diagnosis in theory seem difficult; in practice, however, it is usually more straightforward. The diagnosis of OCD must be made only if the "obsessive worries" are true obsessions, rather than symptoms of another disorder such as depressive ruminations or phobic avoidance. For example, when OCD is comorbid with bulimia or anorexia, the content of the obsessions or compulsions must be typical for OCD, for example, washing, arranging, counting, and repeating, and not be solely overfocused ideas about food or diet. Depressive ruminations and psychotic preoccupations are also distinguished by the negative content (e.g., everyone dislikes me, I fail at everything). Phobic disorders are not only distinguished by the content of the preoccupation (more often heights, spiders, the dark, etc.), but also by the absence of discomfort when the patient is not confronted with the phobic object. It may be more difficult to separate the obsessional concerns of OCD from the fears and worries of generalized anxiety disorder (Brown *et al.*, 1993). Comorbidity of OCD and anxiety disorders is common, so assigning specific symptoms to a specific disorder may be less important than identifying the presence of OCD in a child presenting with generalized anxiety or separation anxiety disorder.

ASD can be differentiated from OCD by its lack of egodystonicity and, in addition, by the content of the preoccupations. For example, in ASD, concerns about danger or contamination occur only rarely, while these are common among children with OCD. Autistic patients also may exhibit obsessive-compulsive symptoms, but these occur within the context of cognitive and psychosocial abnormalities and should not be confused with symptoms of OCD.

The differential diagnosis from Tourette's disorder is problematic, and the two disorders are linked by several neurobiological

features. Distinguishing between a compulsion or a tic may be difficult, given the presence of premonitory urges before tics and the complexity of some motor tics (Miguel *et al.*, 2000). Some 20–80% of patients with clear Tourette's disorder have been reported to have obsessive-compulsive symptoms or OCD, while 24–67% of children with primary OCD have been observed to have comorbid tics (Leonard *et al.*, 1992; Zohar *et al.*, 1992). Tics are seen most often in younger patients, those with acute illness, and in males. Preliminary impressions are that compulsions associated with Tourette's disorder may be more likely to involve symmetry, rubbing, touching, or staring and blinking rituals than washing and cleaning (Baer, 1994; Leckman *et al.*, 1994). Additionally, aggressive and/or sexual thoughts or rituals have been reported as more frequent in patients with tics and OCD than in those with OCD alone (Despert, 1955; Thomsen, 1991; Masi *et al.*, 2005). However, although some features distinguish the two disorders, the overlapping clinical profiles and family studies provide partial support for the speculation that some cases of OCD and Tourette's may be alternate forms of the same disorder. Any Tourette/OCD formulation, however, is likely to be oversimplified but both tic disorders and OCD may be symptoms of basal ganglia-frontal circuitry dysfunction for which genetic, toxic, traumatic, and infectious agents can be etiologic. In particular, the working model of PANDAS involves the origin of both the tics and OCD through an autoimmune response to GABHS.

Theories of etiology

OCD is caused by a combination of biological and psychological factors, with both genetic and environmental influences.

Biological factors

Genetics

OCD is a highly heritable disorder, particularly when it has a childhood onset. Twin studies comparing monozygotic and dizygotic twins find genetic factors to account for around 45–65% of the variance in obsessive compulsive symptoms in children, compared to between estimates of 27–47% for adult onset symptoms (van Grootheest *et al.*, 2005). Similarly, family studies find a 10-fold increase in rates of OCD among relatives of children with OCD, compared to a doubling of rates of OCD among relatives of those with adult-onset OCD (Pauls, 2010). A population-based study similarly showed a stepwise decrease in the risk of having OCD among relatives of OCD probands as the degree of relatedness fell (Mataix-Cols *et al.*, 2013). Thus, while first-degree relatives had around a four- to fivefold increase in risk, it fell to around a twofold increase in second-degree relatives, and even lower in third-degree relatives. The genetic contribution to OCD is increased when there is comorbid tic

disorder, leading to suggestions that this combination might represent a distinct genetic subtype (Hanna *et al.*, 2005).

Initial searches for the specific causative genes focused on genetic variants (or polymorphisms) within genes coding for neurotransmitters implicated in OCD. A meta-analysis of over 100 such studies confirmed an association between OCD and polymorphisms within serotonergic genes (the serotonin transporter and one of the receptor subtypes) and a trend to association with variants within the glutamate transporter gene (Taylor, 2012).

Genome-wide linkage studies try to link genetic variation with OCD and two such studies have examined the families of children with the disorder (Willour *et al.*, 2004; Hanna *et al.*, 2005). They converged to find a region on chromosome 9 to be linked with OCD, which contains many genes, including the glutamate transporter gene. The next phase of genomic studies will involve sequencing of either the entire genome or just its coding regions (exome). Initial steps in this direction have been made with sequencing of the glutamatergic transporter gene and finding that “errors” of coding are increased in those with OCD (Wang *et al.*, 2010). Strategies to accelerate genomic discovery include studying subtypes of OCD, such as those with hoarding disorder, or examining the dimensions of the disorder (Samuels *et al.*, 2002; Hasler *et al.*, 2007).

Twin studies also emphasize the importance of the environment in the etiology of OCD, with around 42–55% of the variance of OC symptoms being explained by nonshared environmental factors (Hudziak *et al.*, 2004). Little is known however of the specific factors at play. In a longitudinal study of children with OCD and controls, psychosocial stressors affecting a child, as reported by parents, predicted later depressive and OC symptom severity (Lin *et al.*, 2007). These environmental factors included self-evaluation of daily stressors and long-term contextual threat. The family environment may also contribute to OCD, particularly the ways in which family members take part in the performance of rituals and help relatives avoid anxiety-provoking situations. Such familial accommodation is associated with OCD symptom severity and its reduction is associated with symptom improvement, a point we will return to as we consider treatment (Lebowitz *et al.*, 2012). Given the evidence of the importance of environmental factors in the etiology and course of OCD, more research is needed in this area to complement ongoing genomic studies.

Neural basis

OCD is remarkable in the consistency of support for a conceptual model which links a disorder characterized by endless, repetitive thoughts and actions with uncontrolled activity of parallel, discrete loops within the brain. These loops connect the basal ganglia, prefrontal cortex—particularly the orbitofrontal and anterior cingulate regions—and thalamus, the so-called cortico-striato-thalamocortical (CSTC) loops—see Figure 61.1 (Alexander *et al.*, 1986; Rapoport & Wise, 1988; Modell *et al.*, 1989; Saxena *et al.*, 2001; Kopell *et al.*, 2004).

Several CSTCs have been assumed to be of particular importance in OCD, based on clinical, imaging, and lesion studies. The first “direct” pathway is in essence a positive feedback loop that results in the initiation and continuation of thought and action. It is counterbalanced by an “indirect” pathway that acts as a check on the activation of the direct pathway. The direct pathway starts with a glutamatergic signal to the striatum which in turn sends an inhibitory GABA-ergic signal to the globus pallidus. This results in a disinhibition of the thalamus which is fed forward to the prefrontal cortex, particularly, orbitofrontal regions. The indirect pathway differs in that the striatum projects an inhibitory signal to the globus pallidus, which increases inhibition on the thalamus and thus decreases prefrontal cortical activation. While there are multiple neurotransmitters involved in this circuit, including substance P and GABA, there are also serotonergic projections to this component from the dorsal raphe to the ventral striatum. These projections are speculated to be inhibitory.

One model holds that OCD arise from primary striatal dysfunction within these loops. This causes deficits in thalamic filtering and in turn increases orbitofrontal cortical activity (Graybiel & Rauch, 2000b). By this reasoning, implicit information is no longer filtered at a striatal level but intrudes into consciousness. A refinement of this model argues for an imbalance between the direct and indirect CTSC loops (Saxena *et al.*, 1998; Mataix-Cols & van den Heuvel, 2006). Thus, OC symptoms emerge when an aberrant positive feedback loop develops in the first circuit, which is inadequately modulated by the output from the second circuit.

The implication of abnormal activity in CSTCs is supported to some degree by findings of structural anomalies within these circuits in children with OCD, although there are some inconsistencies in the findings (for a review see Menzies *et al.*, 2008; Radua *et al.*, 2010). Functional imaging studies also find evidence of dysfunction within CTSC. For example, striatal dysfunction results in abnormal interactions between the dorsal striatum and prefrontal cortical region. This leads to impaired cognitive control and decreased cognitive flexibility, reflected by the ability to adapt to changing task demands. Studies of children with OCD find reduced activation of the dorsolateral prefrontal cortical regions supporting cognitive flexibility and hypoactivation of the right caudate, a direct demonstration of CTSC dysfunction (Woolley *et al.*, 2008; Britton *et al.*, 2010; Rubia *et al.*, 2011). Others have emphasized the role of the orbitofrontal cortex in cognitive control and flexible responding, conceptualizing the failure to resist obsessions and compulsions in OCD as stemming from its dysfunction. In one study, both young adults with OCD and their unaffected siblings showed decreased activation of the lateral orbitofrontal cortex during a task which required them to alter behavior in response to negative feedback. The centrality of the orbitofrontal cortical dysfunction in OCD has derived considerable support from repeated demonstration in adults that symptom provocation is accompanied by increased orbitofrontal cortical activity

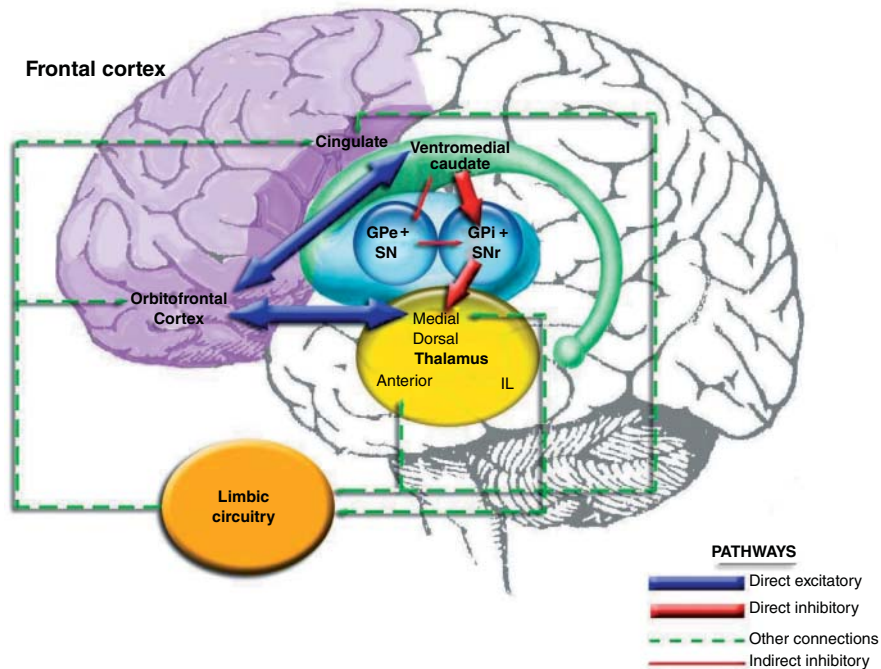

Figure 61.1 The direct and indirect circuitry thought to underlie the pathogenesis of OCD. GPI, globus pallidus pars interna; GPe, globus pallidus pars externa; SNr, substantia nigra pars reticulata. In the **DIRECT** pathway (thick arrows), the frontal cortex projects to the caudate and then to the GPI/SNr complex which provides the main output of the basal ganglia. This in turn projects to the thalamus and finally back to the frontal cortex. The pathway has two excitatory and two inhibitory projections and thus is a net positive feedback loop. This circuit is balanced by the **INDIRECT** pathway (in thin arrows) which has a net inhibitory effect. This differs in its projection from the caudate to the GPe/SN complex (which also receives direct frontal input) before relaying onto the output station of the basal ganglia (the GPI/SNr complex). Interactions with the limbic system occur at several points and have been increasingly recognized in view of deficits in emotional processing and the anxiety prominent in OCD.

(Menzies *et al.*, 2008). However, in the only study to provoke symptoms among children, the opposite pattern of decreased orbitofrontal activation was found (Gilbert *et al.*, 2009).

A second model of OCD views the disorder as the result of overactivation of a system designed to monitor performance completion, leading to a constant feeling that an action is “not just right” which thus creates a need to correct perceived mistakes (Aouizerate *et al.*, 2004). A range of tasks assessing aspects of performance monitoring, error detection, and response to conflicts have converged to show hyperactivity in the anterior cingulate in adults with OCD (van Veen & Carter, 2002; Ursu *et al.*, 2003; Fitzgerald *et al.*, 2005; Maltby *et al.*, 2005). In pediatric OCD such anterior cingulate hyperactivation was reported in two of three studies examining brain activity during tasks of monitoring performance and detecting errors (Fitzgerald *et al.*, 2010; Huyser *et al.*, 2011; Rubia *et al.*, 2011). One of these studies further suggested that this hyperactivation might be more pronounced in adolescence rather than childhood (Huyser *et al.*, 2011).

How specific are these neural substrate to OCD? Similar anomalous interaction between the striatum and prefrontal cortex is also held to be important in ADHD, tic, and other impulse control disorders (see Castellanos & Tannock, 2002; Marsh *et al.*, 2009).

Some degree of overlap is perhaps inevitable, but there are several unique features in the OCD model outlined above, most importantly, the emphasis on an imbalance of the direct and indirect pathways in OCD and the prominence given to glutaminergic neurotransmission.

Neurochemistry

Monoaminergic neurotransmitters which extensively project from the brain stem to regions within the fronto-striato-thalamic circuitry may contribute to the pathogenesis of OCD. OCD symptoms are frequently exacerbated by serotonin agonists (such as *meta*-chlorophenylpiperazine), and the serotonin reuptake inhibitors are the most effective therapeutic agents (Gross-Isseroff *et al.*, 2004). Abnormalities of serotonergic transmission in OCD are suggested by imaging studies of central serotonin receptors using specific ligands which have demonstrated a reduction in 5-HT synthesis in the ventral prefrontal cortex and caudate in 11 treatment-naïve pediatric subjects, which partially normalized following successful treatment (Simpson *et al.*, 2003). Inconsistent findings on the levels of central serotonin transporter availability may be partly attributable to developmental effects, as reports of an increase of central serotonin transporter availability (indexed by the binding profiles of a ligand thought to bind to the transporter) was found

only in those with child- but not adult-onset OCD (Pogarell *et al.*, 2003; Simpson *et al.*, 2003; Stengler-Wenzke *et al.*, 2004). There are less consistent findings for the dopaminergic system, with mixed results concerning changes in peripheral dopaminergic markers and the provocation of obsessive symptoms by dopamine agonists (Denys *et al.*, 2004b). PET neuroimaging studies, however, have demonstrated higher caudate dopamine transporter densities in tandem with lower concentrations of the dopamine D2 receptor, consistent with receptor down-regulation resulting from higher synaptic concentrations of striatal dopamine in adults with OCD (Denys *et al.*, 2004a; van der Wee *et al.*, 2004). Glutamate is the major excitatory neurotransmitter in the fronto-striatal circuitry, and magnetic resonance spectroscopy has demonstrated elevation in levels of glutamate and glutamine in the thalamus of treatment-naïve children with OCD, with a reduction in symptoms occurring in tandem with normalization of the glutamatergic marker (Rosenberg *et al.*, 2000). A decrease in glutamate levels in the anterior cingulate has also been found, although this may not be specific to OCD as it was also seen in children with major depression (Rosenberg *et al.*, 2004). There is, thus, some direct support for anomalous serotonergic neurotransmission and more indirect and somewhat inconsistent evidence of abnormal dopaminergic and glutamatergic signaling.

Treatment approaches

Psychological treatment

The cornerstone of psychological therapies for children is exposure and response prevention (ERP), and its efficacy has been demonstrated in multiple open studies and two randomized controlled trials (Barrett *et al.*, 2004; POTS, 2004). A hierarchy of increasingly intense anxiety-provoking situations that trigger obsessional thinking is constructed and subjects are exposed gradually to these situations and encouraged to refrain from engaging in compulsive behaviors (March & Mulle, 1998). Gradually, the patient progresses through the hierarchy so that situations can be tolerated with minimal anxiety, thus attaining an ever-decreasing urge to engage in compulsions. In clinical practice, and in all controlled studies, ERP is usually combined with other behavioral techniques, such as anxiety management training and extinction (e.g., instructing parents not to give reassurance when a child compulsively seeks it). This makes it difficult to disentangle the relative therapeutic importance of each element. Frequently, cognitive components are added, such as normalizing intrusive thoughts and reappraising notions of personal responsibility. Again, the necessity of these cognitive components is unclear in children as there are no controlled trials comparing these approaches. Tailoring therapy to the symptom profile of the child may be helpful. For example, ERP may be ideal for younger children as it has been shown to be effective in those under 11 and may be particularly helpful for symptoms such as contamination fears and symmetry rituals

(Barrett *et al.*, 2003). By contrast, cognitive approaches may be more suited to the child with obsessional moral guilt or pathological doubt.

The involvement of the family in treatment is essential. Psycho education can help the family to avoid both punitive responses and the alternative family accommodation that can occur if the family becomes enmeshed in rituals. Coercive and disruptive behaviors, and attacks of rage are associated with family accommodation. These disruptive behaviors are often associated with family attempts to limit OCD symptom expression. Behavioral management of these episodes can be critical to successful treatment (Lebowitz *et al.*, 2011; Storch *et al.*, 2012).

While the efficacy of behavior therapy (BT) with ERP as a core component is accepted, the most efficient and efficacious method of providing this treatment is less clear. A randomized controlled study demonstrated that such family-based cognitive behavioral therapy may be equally efficacious when conducted either with individual families or in a group setting (Barrett *et al.*, 2004). The degree of personal contact with the therapist continues to be an important issue given the cost of more intense programs. At one extreme lie computer-based delivery systems, including web camera-based treatment with minimal therapist contact time (Kenwright *et al.*, 2005; Storch *et al.*, 2010). There is also some initial evidence that self-help interventions with no therapist involvement at all are acceptable and effective (Robinson *et al.*, 2012). At the other extreme are highly intensive day or in-patient treatment programs. Only one trial has directly compared once weekly with daily therapy; no significant difference in outcome was found, although this study was not randomized and thus conclusions are limited (Franklin *et al.*, 1998). A meta-analysis suggested that while more therapist-intensive approaches were more efficacious, even those involving relatively little therapist contact time (less than 10 hours) were also effective (National Institute for Health and Care Excellence, 2005). While CBT is a robust frontline treatment overall, about 30% of pediatric populations have little or no response. Poor response is associated with diminished insight, family accommodation, and comorbidity (depression, Tourette's disorder, and cognitive deficits) (Storch *et al.*, 2010). Family accommodation is of particular importance and is worth measuring, monitoring, and tracking in clinical care (Lebowitz *et al.*, 2012). In practice, the severity of the symptom profile, the complexity of comorbidity, and resources available within the family and local health care services are likely to determine the treatment intensity. Many countries also have self-help groups which provide a valuable source of support and information, as well as act as advocates for those living with the disorder.

Pharmacotherapy

There is a relative abundance of randomized controlled trials demonstrating the efficacy of clomipramine and selective serotonin reuptake inhibitors—SSRIs (sertraline, fluoxetine, paroxetine and fluvoxamine)—in the acute phase treatment of childhood OCD, reviewed in Table 61.3.

Table 61.3 Controlled studies of medication in the treatment of pediatric OCD.

Study	Design	Participants	Interventions	Outcomes
Clomipramine				
Deveaugh-Geiss <i>et al.</i> (1992)	RCT, 8 weeks	<i>N</i> = 60, mean age = 14	Clomipramine versus placebo	Mean reduction in Yale–Brown Obsessive Compulsive Scale score of 37% compared to 8% in the placebo group. Sustained at 1 year
Greist <i>et al.</i> (1990)	RCT, 8 weeks	<i>N</i> = 16, mean age = 15	Clomipramine versus placebo	1 (73%) improved, 5 (33%) improved by more than 50%, and none worsened. Only 2 (12.5%) of the 16 placebo-treated patients improved, 1 (6%) by more than 50%; two (13%) worsened
Flament <i>et al.</i> (1985)	Cross-over, 5 weeks in each treatment	<i>N</i> = 27, mean age = 14	Clomipramine versus placebo	Clomipramine significantly more effective than placebo in reduction on all symptom scores
Leonard <i>et al.</i> (1989)	Cross-over, 5 weeks in each treatment (DB) and 2 weeks on placebo (single-blind SB)	<i>N</i> = 49, mean age = 14	Clomipramine versus desipramine versus placebo	Clomipramine significantly more effective than desipramine in symptom reduction. Higher rate of relapse when desipramine was substituted for clomipramine
SSRIs				
POTS (2004)	RCT, DB 12 weeks	<i>N</i> = 112, mean age = 12	CBT versus CBT + sertraline versus sertraline	Combined treatment also proved superior to CBT alone and to sertraline alone which did not differ from each other. CBT alone was associated with (nonsignificantly) higher rates of remission than sertraline
March <i>et al.</i> (1998)	RCT, DB 10 weeks	<i>N</i> = 189, mean age = 13	Sertraline versus placebo	Sertraline produced significantly greater improvement in CY-BOCS. Based on CGI-I ratings at end point, 42% of patients receiving sertraline and 26% of patients receiving placebo were very much or much improved. Neither age nor sex predicted response to treatment
Geller <i>et al.</i> (2001)	RCT, DB 13 weeks	<i>N</i> = 103, mean age = 11	Fluoxetine versus placebo	Fluoxetine produced significantly greater improvement in CY-BOCS (fall of 9.5 points compared to 5.2 for placebo)
Liebowitz <i>et al.</i> (2002)	RCT, DB 12 weeks	<i>N</i> = 43, mean age = 13	Fluoxetine versus placebo	No significant difference at 8 weeks; but by 16 weeks, fluoxetine was associated with greater reduction in CY-BOCS (9.74 points) than was placebo (4.14 points)
Riddle <i>et al.</i> (1992)	Cross-over DB 16 weeks	<i>N</i> = 14, mean age = 12	Fluoxetine versus placebo	CY-BOCS total score decreased 44% (<i>N</i> = 7, <i>p</i> = 0.003) after the initial 8 weeks of fluoxetine treatment, compared with a 27% decrease (<i>N</i> = 6, <i>p</i> = 0.13) after placebo
Geller <i>et al.</i> (2004)	RCT, BD 10 weeks	<i>N</i> = 207, mean age = 11	Paroxetine versus placebo	Paroxetine produced significantly greater improvement in CY-BOCS (fall of 8.78 points compared to 5.34 points in placebo group)
Riddle <i>et al.</i> (2001)	RCT, DB 10 weeks followed by 1-year open label extension	<i>N</i> = 120, mean age = 13	Fluvoxamine versus placebo	The CY-BOCS total score decreased 44% after the initial 8 weeks of fluoxetine treatment, compared with a 27% decrease after placebo

Note: RCT = randomized clinical trial; DB = double-blind; SD = single-blind

A meta-analysis of 12 studies of SRIs and clomipramine found all medications to be superior to placebo and found that clomipramine showed superiority over all the SRIs which did not differ from one another (Geller *et al.*, 2003). However, clomipramine is associated with several adverse side effects, including potential arrhythmogenic effects.

Although generally well tolerated, SSRIs are associated with a range of side effects, with nausea, headache, and agitation being common to all in this class. There are widespread concerns about adverse somatic effects of medication in children, and reports of increase suicidal ideation. In some cases, however CBT is not possible to implement without concomitant medication, or not

effective. Moreover in many countries the cost of CBT and/or unavailability of this treatment may also be a limiting factor.

Depression is highly comorbid with OCD, and the treatment of this combination is often challenging. Two studies have found that adding imipramine (Foa *et al.*, 1992) or SRIs (Abramowitz *et al.*, 2000) either before or during ERP may be effective for alleviating depressive symptoms but did not potentiate ERP. There are case reports supporting the use of cognitive therapeutic techniques to increase motivation and compliance in the depressed patient to help them engage with difficult exposure assignments (Abramowitz, 2004).

In children, low initial doses with slow upward titration is the rule. In adults, higher doses are clearly associated with improved treatment efficacy without significant increase in adverse events (Bloch & Leckman, 2010) but this has not been systematically studied for pediatric populations. Patients should be made aware of the common side effects and the need for a 12-week treatment trial. Partial or complete failure to respond to the first SRI should prompt treatment with BT and consideration of another SRI. Use of augmenting agents for youths with treatment-resistant OCD is discussed below.

Combination treatment

How do pharmacological and psychological treatments compare? The best current evidence comes from the Pediatric OCD Treatment (POTS) multicenter study which randomized 112 children to either sertraline, cognitive behavioral therapy (CBT), the treatments combined, or pill placebo for 12 weeks (POTS, 2004). All active treatments were superior to pill placebo. Combined treatment also proved superior to CBT alone and to sertraline alone, which did not differ from each other. Site differences emerged for CBT and sertraline but not for combined treatment, suggesting that combined treatment is less susceptible to setting-specific variations, and, given this generalizability, combined treatment may be the option of choice. Notably, there was no evidence of treatment-emergent suicidality. Much smaller studies similarly found that a combination of BT (based on enterprise resource planning (ERP)) and fluvoxamine was superior to medication alone, both in short-term response and at a follow-up period of 1 year (Neziroglu *et al.*, 2000). A direct comparison of BT with clomipramine in 22 children found a nonsignificant superiority for psychotherapy (de Haan *et al.*, 1998). Overall, it is clear that while medication alone is effective and generally safe and well tolerated, CBT may have the edge in terms of a first-line treatment, particularly when combined with an SSRI or clomipramine. Double-blind trials of D-cycloserine augmentation of CBT in pediatric OCD subjects have yielded mixed results, with one study finding benefit over placebo, and one not (Storch *et al.*, 2010; Farrell *et al.*, 2013).

Augmenting strategies for partial responders

Up to 50% of children will show only a partial response to initial SRI treatment (Geller *et al.*, 1998). The POTS study mentioned earlier found that around 60% of children receiving CBT alone, 46% receiving combined CBT and SRI, and approximately 80% receiving SRI alone do not fully remit (POTS, 2004). For adults showing such suboptimal response to an SRI, several trials have shown a significant reduction of obsessive symptoms in patients with either adjunctive haloperidol or risperidone (McDougle *et al.*, 2000; Li *et al.*, 2005). In treatment-resistant adult OCD patients, second-generation antipsychotics such as quetiapine have been reported to be effective augmenting agents (Kordon *et al.*, 2008). Other treatment strategies in adults include augmentation with clonazepam or oral morphine or combining two SRIs, (for a review see Walsh and McDougle,

2004). There are some case reports demonstrating the potential for the use of each of these strategies in children, although there are no controlled studies to guide the clinician in this complex field (Leonard *et al.*, 1994; Lombroso *et al.*, 1995; Figueroa *et al.*, 1998). Clearly, the side effects of each augmenting agent need to be considered, particularly the risk of tardive dyskinesia with haloperidol, metabolic side effects of risperidone, or other antipsychotic agents, and risk of tolerance and dependence with clonazepam. Recent double-blind studies of N-acetylcysteine (NAC), an antioxidant precursor to glutathione, have shown significant benefit using 1200–2400 mg/day, in adult patients with OCD, as well as with trichotillomania or skin picking (Afshar *et al.*, 2012). The actions are poorly understood but NAC has been shown to alter neurotransmitters including glutamate.

In spite of the major advances in drug treatment, at least 10% of the OCD population remains severely affected. In adults, for extreme cases there is an option for neurosurgical procedures, which are aimed at disrupting the CSTC loops either through creating a permanent lesion through excision or through repetitive deep brain stimulation (Greenberg *et al.*, 2003). Such physical therapies are not appropriate for children; less invasive alternatives such as transcranial magnetic stimulation, while giving insight into the abnormal responsivity of the motor cortex in OCD (Gilbert *et al.*, 2004), have not proved effective in the treatment of adults and remain untested in children (Martin *et al.*, 2003).

Maintenance treatment

OCD is frequently a chronic disorder and long-term maintenance therapy should be anticipated, with the current recommendation being a minimum treatment period of 6 months following full remission. The need for such maintenance was illustrated by an 8-month study of 26 children and adolescents with severe OCD who had received clomipramine for a mean of 17 months; a 2-month double-blind desipramine-substitution phase resulted in 89% of the substituted (versus 18% of the non-substituted) subjects relapsing during the substitution phase (Leonard *et al.*, 1991).

Immunomodulatory treatments

Based on the observation that some childhood onset OCD patients had onset apparently related to infection with GABHS, a subgroup of children were proposed who were hypothesized to have an autoimmune based form of the disorder—PANDAS (Swedo *et al.*, 2004). As a partial test of this model, two treatments were examined. A controlled treatment trial of intravenous immunoglobulin was carried out, together with an open trial of plasmapheresis (Perlmutter *et al.*, 1999b). Both treatments were effective in lessening of symptom severity for children with infection-triggered OCD and tic disorders. Penicillin or azithromycin prophylaxis of sufficient intensity to decrease streptococcal infections was also found to decrease neuropsychiatric symptom exacerbations among children in the

PANDAS subgroup (Snider *et al.*, 2005). This study is limited by the absence of a placebo control, particularly as a previous placebo-controlled trial using penicillin prophylaxis was negative (Garvey *et al.*, 1999). These fascinating findings have yet to be replicated but raise the possibility of the prevention of OCD in at least a subset of children with the disorder.

Conclusions

Public awareness of OCD has increased greatly over recent years, allowing this once “secret” disorder to be more readily recognized both by families and mental health professionals. Functional neuroimaging studies increasingly inform and refine models of the pathogenesis of the disorder, and are being matched by neuroanatomic imaging studies which allow a delineation of structural change at an ever-decreasing level of resolution. While candidate gene studies have provided some validation of the implication of monoaminergic anomalies in the disorder, the application of new technologies to scan the entire genome is likely to provide novel insights into the genetics of OCD. Of most practical importance, though, are the strengthening of the evidence base for treatment through recent large-scale double-blind trials and the renewed interest in the management of those with treatment-resistant symptoms. The strides in understanding the neurobiology of the disorder are thus matched by definitive demonstrations of treatment efficacy in children, and make it all the more important that children, parents, and health care professionals remain aware of the disorder and the availability of effective treatments.

CHAPTER 62

Bipolar disorder in childhood

Ellen Leibenluft¹ and Daniel P. Dickstein^{2,3}

¹Section on Bipolar Spectrum Disorders, Emotion and Development Branch, National Institute of Mental Health, Bethesda, MD, USA

Introduction

Bipolar disorder (BD) is among the most impairing childhood psychiatric illnesses. In the last two decades, there has been a marked upsurge in knowledge about childhood-onset BD.

In this chapter, we first review data on the *characteristics and diagnosis* of childhood-onset BD, including its phenomenology, distinction from typical development, impact on functioning, and differential diagnosis. We then describe *assessment* of BD, including comorbid psychopathology such as attention deficit hyperactivity disorder (ADHD). Then, we discuss its *epidemiology, longitudinal course, and risk factors*, before summarizing recent data about the *pathophysiology and treatment* of childhood-onset BD. We conclude by predicting *future directions* for research and clinical care for childhood-onset BD.

Characteristics and diagnosis of the condition

Phenomenology

At its core, BD is a mood disorder involving a change from baseline normal mood to elevated, expansive, or irritable mood plus concomitant behavioral changes (section “Diagnosis in DSM, ICD, elsewhere”). Some forms of BD also require depressive episodes.

Distinction between normal and pathological

Episodes of mania and depression differ from normal fluctuations in mood and behavior because they last longer, are associated with other symptoms (e.g., “B” symptoms of mania or neurovegetative dysfunction in depression), and cause impairment, including disruptions of peer, occupational/educational, and family function.

Cultural issues

Relatively little is known about cultural differences in the phenomenology of childhood-onset BD. More such studies are needed, evaluating the impact of culture on the expression and treatment of BD.

Diagnosis in DSM, ICD, elsewhere

In the Diagnostic and Statistical Manual 5th edition (DSM-5), a diagnosis of BD is based on the presence of manic, hypomanic, and major depressive episodes (American Psychiatric Association, 2013). A manic episode involves elevated, expansive, or irritable mood that should be different than the child’s baseline mood. Concomitant with the mood change additional symptoms should include decreased need for sleep, increased goal-directed activity [e.g., persistently practicing singing all day long and ignoring other activities], and flight of ideas [e.g., thoughts jumping from topic to topic without logical connection]. The duration of the mood change plus associated symptoms must be at least seven days or require hospitalization for a manic episode, or four to seven days for a hypomanic episode.

Importantly, the mood and activity changes need to represent an episode—that is, a clear period of altered function by comparison with the young person’s usual state. It should be clear that they are present throughout the day and occur nearly every day during the episode. The associated features also need to have appeared (or worsened) during the episode, and do not reflect simply the ordinary condition of the young person. Episodicity is therefore an important part of the definition: an episode should last for at least a week to constitute a manic period (and may last for much longer). A hypomanic episode is a period lasting a shorter time—4–7 days of these mood and activity changes and associated features.

A major depressive episode consists of depressed mood or decreased interest or pleasure most of the day, nearly every day during a 2-week period, representing a change from previous functioning, and accompanied by additional symptoms, for example, recurrent thoughts of death and inability to experience pleasure ["anhedonia"]. DSM-5 has a child-specific modification allowing irritable, rather than depressed, mood to fulfill the mood criterion for a major depressive episode. A mixed episode is diagnosed when full criteria are met for both a manic and major depressive episode for at least 1 week (see also Chapter 63). If irritability is the only mood change, the diagnostician should remember that it is not very specific to mania (see Chapter 5) and care is needed in assessment.

DSM-5 recognizes three types of BD, based on lifetime history of episode type: type I requires at least one manic episode (no major depressive episode required), type II requires at least one hypomanic episode plus at least one major depressive episode; and "not otherwise specified" (BD-NOS) includes patients whose symptoms do not meet criteria for a specific type of BD, including but not limited to patients whose symptoms do not satisfy duration criteria for a manic or hypomanic episode.

Three issues make establishing the diagnosis of BD difficult in children: (i) duration of a manic episode, (ii) the role of irritability versus euphoria in defining a manic episode, and (iii) overlap with other illnesses, including ADHD. Changes from DSM-IV to DSM-5 are meant to address these issues.

Regarding duration, DSM-5 has a substantive change from DSM-IV-TR in now requiring that irritable or euphoric mood in mania/hypomania should last "most of the day nearly every day" akin to DSM-IV and DSM-5 specifications of a major depressive episode. This language applies regardless of the patient's age—that is, to children and to adults equally. This change is designed to refute prior assertions that BD in children or adolescents is a chronic illness, with fluctuations between all three mood states often occurring within a single day (e.g., "ultradian cycling") (Geller *et al.*, 1998; Biederman *et al.*, 2004). Instead, this promotes the classical view that BD in both children and adults is an episodic illness, with distinct periods (days to weeks) of mania, depression, and euthymia (Leibenluft *et al.*, 2003; Birmaher *et al.*, 2006).

Second, euphoric mood is unique to mania, but it is not necessary for the diagnosis in DSM-5, which allows irritable mood to fulfill this criterion. Irritability and euphoria are weighted differently, so that three associated "B" symptoms are required if the mood is primarily euphoric, and four if the mood is primarily irritable. Moreover, irritability is a diagnostic criterion not only for mania, but also for several other disorders including generalized anxiety disorder, the child-specific modified criterion for a major depressive episode, and oppositional defiant disorder (ODD). Irritability is also an associated symptom for disorders including autism-spectrum disorders and ADHD (American Psychiatric Association, 2000). Unlike DSM-IV, DSM-5 has attempted to clarify how irritability differs among disorders. For example, in DSM-5, irritability in

mania must occur simultaneously with "B" symptom changes (e.g., decreased need for sleep).

The third DSM-related factor leading to potential confusion is the overlap between some of the associated features of mania and those of ADHD. For example, how does one distinguish pressured speech in mania from talking excessively and blurting out answers in ADHD? How to distinguish distractibility in mania from distractibility in ADHD? Unlike DSM-IV, DSM-5 builds on work by Geller *et al.* who found that five symptoms best distinguished children with BD from those with ADHD [(i) elation, (ii) grandiosity, (iii) hypersexuality, (iv) flight of ideas/increased goal-directed activity, and (v) decreased need for sleep], to now require that these "B" symptoms only count toward a diagnosis of mania if they are present during the episode of mood and activity/energy change (Geller *et al.*, 2002a, b).

In contrast, ICD-10's approach to BD is more conservative than that of the DSM. Specifically, it requires elation in a manic or hypomanic episode, as well as two or more episodes of hypomania, mania, or depression to establish the diagnosis of bipolar affective disorder. With regard to children specifically, the UK's National Institute for Health and Care Excellence (NICE) BD guidelines state that the same criteria should be used to diagnose BD in children as in adults, except that (i) mania must be present (not just hypomania), (ii) euphoria must be present most days, most of the time for at least 7 days, and (iii) consistent with ICD-10, while irritability can be helpful in making a diagnosis of BD if it is severe, episodic, uncharacteristic, and results in functional impairment, it should not be considered a core diagnostic criterion (NICE, 2006).

Impact of the disorder on functioning

BD in childhood is associated with significant morbidity and mortality, including high rates of psychiatric inpatient hospitalization (more than 52–74% hospitalized at least once), suicidal ideation (70–85%), and suicide attempts (30–65%) (Axelson *et al.*, 2006; DelBello *et al.*, 2007; Algorta *et al.*, 2011a).

Differential diagnosis

The differential diagnosis for childhood-onset BD includes any disorder involving euphoria, irritability, or depression as well as psychosis. This includes substance intoxication and substance-related mood or psychotic disorders. It also includes primary medical problems including toxidromes (e.g., anticholinergic ingestion resulting in psychosis/mania), thyroid abnormalities (e.g., hypothyroidism/depression, or hyperthyroidism/mania), or seizure disorders (temporal lobe epilepsy).

In particular, we note the new DSM-5 diagnosis "Disruptive Mood Dysregulation Disorder" (DMDD) that should be considered in the differential of children with functionally impairing irritability. Unlike BD, DMDD involves chronic, severe irritability characterized by (i) frequent temper outbursts out of proportion to the situation and child's developmental

Table 62.1 Severe mood dysregulation (SMD) diagnostic criteria.

Inclusion criteria

- 1 Age 7–17 years, with symptom onset before age 12.
- 2 Abnormal mood (specifically, anger or sadness) present at least half of the day most days and of sufficient severity to be noticeable by others (e.g., parents, teachers, or peers).
- 3 Hyperarousal, as defined by ≥ 3 : insomnia, agitation, distractibility, racing thoughts or flight of ideas, pressured speech, or intrusiveness.
- 4 Compared to peers, the child exhibits markedly increased reactivity to negative emotional stimuli manifest verbally or behaviorally—that is, temper tantrums out of proportion to the inciting event and/or child's developmental stage—occurring >3 times/week during past 4 weeks.
- 5 Symptoms are present for ≥ 12 months without ≥ 2 months symptom-free.
- 6 Symptoms are severe in ≥ 1 setting and mild in a second setting.

Exclusion criteria

- 1 Child has any “cardinal” BD symptoms: elevated/expansive mood, grandiosity, or episodically decreased need for sleep.
- 2 Distinct episodes ≥ 4 days.
- 3 Individual meets diagnostic criteria for schizophrenia, schizophreniform disorder, schizoaffective illness, pervasive developmental disorder, or post-traumatic stress disorder.
- 4 Individual meets criteria for substance use disorder in the past 3 months.
- 5 IQ < 80 .
- 6 Symptoms are direct physiological effect of drug of abuse or general medical/neurological condition.

level, manifest verbally or physically, and occurring frequently (e.g., three or more times per week) and (ii) persistently irritable or angry mood (Table 62.1).

DMDD was added to the DSM nosology based on work demonstrating that children with chronic irritability represent a unique population compared to those with episodic euphoria. Specifically, Leibenluft *et al.* operationalized criteria for severe mood dysregulation (SMD) (Table 62.1) to determine if children with chronic irritability differ from those with classic BD and episodic euphoria (“narrow-phenotype BD” [NP-BD] (American Psychiatric Association, 2000; Leibenluft *et al.*, 2003). In contrast to other DSM disorders where irritability is not operationalized clearly, SMD criteria define it as temper outbursts (i.e., markedly increased reactivity to negative emotional stimuli manifest verbally or behaviorally) and an abnormally sad or angry baseline mood (i.e., present most days, most of the time).

Over the past decade, over 150 NP-BD and 200 SMD youths have been studied. Both SMD and NP-BD youths do not differ on initial evaluation in impairment, number of psychiatric medications, and number of psychiatric hospitalizations. Prospectively, only one of 84 SMD subjects (1.2%) experienced a (hypo)manic or mixed episode during a median 28.7 months of follow-up, whereas 58 of 93 NP-BD participants (62.4%) experienced such an episode (Stringaris *et al.*, 2010a).

Brotman *et al.* (2006) conducted a post hoc analysis of data from the Great Smokey Mountain Study (GSMS), a longitudinal, population-based community survey. The lifetime prevalence of

SMD among children 9–19 years old ($N = 1420$) in the first wave was 3.3% (Brotman *et al.*, 2006). Children who met SMD criteria during the first wave (mean age 10.6 ± 1.4 years) were more likely to be diagnosed with a depressive disorder during young adulthood than those who never met SMD criteria (mean age 18.3 ± 2.1 years; OR 7.2, CI 1.3–38.8, $p = 0.02$) (Brotman *et al.*, 2006). This suggests that SMD in childhood is associated with unipolar depression, rather than BD, later in life.

This aligns with another study of 631 participants whose parents were interviewed when participants were in early adolescence (mean age = 13.8 ± 2.6 years) and who were themselves interviewed 20 years later (mean age = 33.2 ± 2.9 years). While irritability in adolescence predicted MDD (odds ratio = 1.33, 95% CI = 1.00–1.78), generalized anxiety disorder (OR = 1.72, 95% CI = 1.04–2.87), and dysthymia (OR = 1.81, 95% CI = 1.06–3.12) at 20-year follow-up, it did not predict BD in adulthood (Stringaris *et al.*, 2009). Other longitudinal studies confirm the association between irritability (often in the form of ODD) and subsequent unipolar depression and/or anxiety disorders, rather than BD (Copeland *et al.*, 2009; Rowe *et al.*, 2010).

Disentangling the differential diagnosis of BD in children requires a careful psychiatric history with the children and their primary caretakers; screening for medical or substance-related conditions; collateral sources of information (e.g., teachers, primary care doctor, other mental health providers); and repeat assessments.

In general, unlike anxiety disorders, irritability in mania is not the result of worry or fear. Distinguishing whether a child has primary BD, primary ADHD, or both is complicated (see Section “Diagnosis in DSM, ICD, elsewhere”). Although psychosis can accompany either mania or depression, psychosis unaccompanied by mania or depression suggests either schizophrenia or schizoaffective disorder.

Summary

Recent nosological changes in DSM-5 align with prior research that uses the same diagnostic techniques as in adult studies and confirms that BD in childhood involves episodes of euphoria (in addition to irritability) and clearly defined episodes meeting DSM-IV duration criteria (Findling *et al.*, 2001; Birmaher *et al.*, 2006; Dickstein *et al.*, 2007). However, children with BD do tend to cycle more frequently than adults with BD, and all studies agree that childhood-onset BD is a very impairing illness, leaving affected children symptomatic much of the time.

Assessment

Core aspects

Assessing a child for BD requires determining whether a child has had episodes of mania and depression. Once episodes are identified, the interviewer must determine if the features associated with mania or depression (e.g. sleep and activity changes, increased distractibility, etc.—the “B” criteria of

DSM-5) occurred concurrent with mood changes. If the family cannot identify distinct episodes, then the appropriateness of the diagnosis of BD is called into question.

Euphoria should exceed that which a typically developing child experiences in a very exciting situation, such as going to Disneyland, and true grandiosity should be distinguished from developmentally appropriate fantasy or oppositional behavior. Grandiosity or euphoria should represent a distinct change from the child's usual level of function, and should occur at the same time as other manic symptoms (e.g., decreased need for sleep, increased goal-directed activity). Decreased need for sleep should be differentiated from more typical insomnia, whereby youth would prefer to sleep and may nap during the day.

When possible, clinicians should see a child when the parent states that the child is exhibiting manic behavior. A longitudinal approach may be required, with data from multiple informants including parents and other significant caregivers, such as teachers, and with the child seen repeatedly over time. Prospective daily mood ratings and commonly available technology may help, including cell phone camera recordings of manic or depressive behavior, so that clinicians and parents can achieve a shared understanding of target behaviors and symptoms.

Clinicians must balance concerns about over- and underdiagnosis of BD. A longitudinal approach is required, because children who initially present with one diagnosis, such as unipolar depression or ADHD, might subsequently develop mania. Careful follow-up is particularly warranted in youth with a family history of BD.

Comorbid illnesses should be diagnosed only if symptoms are present when the patient is not in an acute mood episode. For example, a child with BD should be diagnosed with ADHD only if ADHD symptoms are present when he/she is euthymic or subsyndromally ill. Family history of BD in a first-degree relative raises concern about BD in the child; however, children should be diagnosed and treated on the basis of their own clinical presentation. For example, in the Course and Outcome of Bipolar Youth (COBY) study, a prospective study of children with BD types I, II, and NOS, most children with BD had first-degree relatives with unipolar major depression or anxiety, and not BD (Axelson *et al.*, 2006).

Common pitfalls and how to avoid them

The most common pitfall in assessing a child for the presence of BD occurs when the child exhibits for no episodes of mania, despite concerning symptoms, such as severe irritability. This raises questions about the most appropriate course of action. The answer to such questions is to treat the child, not for BD, but for diagnoses that are clearly present. BD can remain on the differential diagnosis for ongoing longitudinal assessment if suspicion remains. Another common pitfall occurs when trying to determine if an irritable outburst is part of typical development, mania, or another disorder. However, mania has a specific duration plus concomitant mood change and other "B" symptoms, whereas irritable/temper outbursts do not.

Use of rating scales, diagnostic interviews, and standardized observations

Currently there are no well-validated rating scales that are sensitive and specific to BD in children. Galanter and colleagues' comparison of six research diagnostic interviews highlights the problems associated with the standardized assessment tools currently available (Galanter *et al.*, 2012). These authors reported considerable variation in how each interview conceptualized the mood criterion, whether the symptoms had to represent a change from the patient's usual state, and whether B-symptoms had to co-occur with the A (mood) symptoms (Young *et al.*, 1978). With regard to parent-rated questionnaires, Faraone *et al.* found that the Child Behavior Checklist (CBCL) "juvenile BD phenotype" (i.e., T-scores greater than 70 on the attention problems, aggression, and anxiety/depression subscales) had acceptable sensitivity and specificity in identifying BD (Faraone *et al.*, 2005). However, other studies indicate that the CBCL does not specifically identify BD youths (Hazell *et al.*, 1999; Boomsma *et al.*, 2006; Youngstrom *et al.*, 2005; Volk & Todd, 2007). Based on this nonspecificity, Althoff *et al.* (2012) have suggested that this be renamed the CBCL "dysregulation profile."

This is an important and active area of investigation. For example, in $N = 2252$ US youths presenting either at an urban academic medical center ($N = 813$) or urban community mental health center ($N = 1439$), the 10-item version of the Parent-report General Behavior Inventory (PGBI-10M) discriminated childhood-onset BD from other diagnoses better than chance (AUROC = 0.79) (Freeman *et al.*, 2012). However, the PGBI-10M requires further investigation and should not be used routinely to screen children for mania.

Coexisting problems: ADHD, anxiety, ODD/CD, and learning disabilities

Comorbidity is the rule rather than the exception in childhood BD. Across studies, more than 70% of children with BD also have ADHD. Anxiety disorders range from 14–76%, ODD from 46–80%, and conduct disorder from 12–41% (Wozniak *et al.*, 1995; Geller *et al.*, 2002a; Harpold *et al.*, 2005; Axelson *et al.*, 2006). Substance abuse disorders have received little attention, although one study found that 32% of adolescents with BD ($N = 57$) had substance use disorder (Wilens *et al.*, 2004). It is possible that referral bias may affect these data, with clinical samples involving sicker children resulting in elevated rates of comorbidity. However, the question remains as to whether these are truly comorbid psychiatric disorders—that is, fully present in their own right—or if they represent using a separate label to capture the same symptoms. In clinical care and research studies, the truest assessment of comorbid psychopathology comes from examining a period of euthymia to determine if symptoms of co-occurring disorders are present when symptoms of mania and/or depression abate.

Family and school context

Multiple impairments have been reported in the families of BD youth, including decreased family function and maternal warmth, and increased expressed emotion, conflict, and family stress (Esposito-Smythers *et al.*, 2006; Miklowitz & Scott, 2009; Algorta *et al.*, 2011b). A variety of neurocognitive deficits have been found in children with BD and associations have been demonstrated with academic difficulties (Pavuluri *et al.*, 2006).

Physical investigations

Currently there is no laboratory test or scan that is diagnostic of BD. Selective laboratory studies may be warranted to exclude medical conditions from the differential diagnosis, particularly hyperthyroidism and substance intoxication/ingestion.

Summary and conclusions

Assessing children for BD requires integrating information from many sources to assess specific diagnostic symptoms and whether they are developmentally appropriate and/or functionally impairing. A longitudinal perspective is particularly important in ensuring the presence of episodes.

Epidemiology

Incidence and prevalence

Broadly, epidemiological studies demonstrate that childhood-onset BD is not so rare, with prevalence being less than that of ADHD (3.7%) but more than either panic disorder or generalized anxiety disorder (0.7%) or eating disorders (0.1%) (Merikangas *et al.*, 2010). However, methodological differences among studies—for example, whether children alone or children and parents were assessed and/or whether BD-NOS was included or not—may falsely make it appear that most BD cases start in childhood.

A recent meta-analysis of epidemiological studies of children and adolescents with BD published from 1985 to 2007, including 16,222 youths from six US studies and six non-US studies, found that the overall rate of BD was 1.8% (range 1.1–3.0%). Importantly, they found no significant difference in mean rates between US and non-US studies. However, studies using broad definitions of BD, including BD-NOS, did report the highest prevalence estimates, and the US studies had a wider range of rates. Controlling for study methodological issues, they did not find a significant increase in rates of childhood-onset BD over time between 1985 and 2007 (Van Meter *et al.*, 2011).

As expected, the prevalence of BD increases from childhood to adulthood. For example, Merikangas *et al.* (2012) conducted a cross-sectional survey of 10,123 US adolescents which showed that 2.5% met criteria for lifetime BD-I or BD-II, with a nearly twofold increase in mania comparing 13–14-year-olds to 17–18-year-olds. However, this study used a modified version of

the Composite International Diagnostic Interview administered to adolescents, without corroboration from parental informants, which may result in overdiagnosis (Merikangas *et al.*, 2012). Lewinsohn's longitudinal studies corroborate this finding, with 1.1% of adolescents ($N = 1507$) meeting criteria for BD when both parents' and children's reports were assessed, while 2.1% of a subset reassessed using only individual report at age 24 ($N = 893$) did so (Lewinsohn *et al.*, 1995; Lewinsohn *et al.*, 2000).

These data align with those of prior cross-national epidemiologic studies of adults showing a lifetime prevalence of 1–3% for BD (Weissman *et al.*, 1996; Kessler *et al.*, 2005). Two large epidemiologic studies of BD adults report a median onset age of 18 (Christie *et al.*, 1988) or 25 (Kessler *et al.*, 2005) years. However, studies indicate that BD age of onset is not distributed normally, with two studies (Bellivier *et al.*, 2003; Lin *et al.*, 2006) each reporting three peaks of onset age. Early onset may be familial or associated with a strong family history of BD (Kennedy *et al.*, 2005; Lin *et al.*, 2006). However, these data are subject to recall bias since they are retrospective recalls of BD-onset, rather than prospective data collected from children.

Global and time variations

Despite the abovementioned meta-analysis by Van Meter *et al.* suggesting similar rates of BD among US and non-US child studies, we know little about global differences in morbidity, mortality, and service utilization resulting from BD in children and adolescents.

Methodological questions

While epidemiological studies with standardized assessments of BD have shown relative stability in BD among children and adolescents over time, clinical studies suggest that increasing numbers of children are being diagnosed with BD. For example, the percentage of minors discharged from psychiatric hospitals in the United States with a diagnosis of BD has surged from less than 10% in the mid-1990s to more than 20% in the mid-2000s (Blader & Carlson, 2007). Another study demonstrated a 40-fold rise in the incidence of US outpatient visits assigned the diagnosis of BD during a similar period, from 25/100,000 in 1993–1994 to 1003/100,000 in 2002–2003 (Moreno *et al.*, 2007). This phenomenon may not be restricted to the United States, with one study showing that rates of under-19-year-olds admitted to German psychiatric hospitals increased 68.5% between 2000 and 2007, an increase which exceeded that for other diagnoses (Holtmann *et al.*, 2010).

Public health implications

From a public health perspective, the inconsistency between epidemiological data suggesting relative stability in rates of children and adolescents diagnosed with BD and clinical data suggesting increasing numbers of youth globally being diagnosed with BD supports the need for more specific tools that clinicians can

employ to effectively diagnose mania and BD. Without them, we run the risk of over, under, and misdiagnosis and potentially incorrect or suboptimal treatment of children and adolescents.

Summary

Inconsistencies between epidemiological and clinical samples highlight the need for the development of assessment tools that can be used in research and in the clinic to evaluate children for BD.

Longitudinal outcome

Methodological factors

Longitudinal studies are clearly needed to determine what happens to children with BD as they become adolescents and ultimately adults. Specifically, there is a need to have samples of BD youths with distinct episodes of mania and hypomania satisfying DSM criteria for BD-I and II, as well as for those with BD-NOS. It also includes the need for comparative studies of BD youths versus those with chronic nonepisodic irritability. However, as illustrated below, variations in how researchers conceptualize the illness may shape their data.

For example, COBY is a longitudinal study of children with BD type I or II, or BD not otherwise specified (BD-NOS). COBY used DSM-IV definitions for BD-I and II. They also operationalized criteria for BD-NOS: (A) clinically relevant BD symptoms of euphoric or irritable mood lasting a minimum of 4 hours within a 24 hour period; (B) at least 2 “B” symptoms if the mood was primarily euphoric (three if primarily irritable), and (C) at least four cumulative lifetime days meeting these criteria. COBY’s focus was thus on children with episodes of mania of varying duration.

The COBY study found that at intake, BD-I ($N = 255$), BD-II ($N = 30$), and BD-NOS ($N = 153$) participants did not differ in age of onset, duration of illness, rates of comorbid disorders, suicidal ideation, or manic symptoms during the most serious episode. Elevated and/or expansive mood was found in 91.8% of BD-I and 81.9% of BD-NOS participants. BD-I participants had more severe manic symptoms, greater overall functional impairment, and higher rates of psychiatric hospitalization, psychosis, and suicide attempts than those with BD-NOS (Axelson *et al.*, 2006). However, 4-year longitudinal follow-up data indicate that BD-NOS participants had significantly longer mean time to recovery from the index episode and significantly longer mean time to recurrence. Thus, COBY data indicate that children do have episodes of mania including both euphoria and irritability (Hunt *et al.*, 2013). Moreover, COBY has shown that BD can be reliably diagnosed in children and adolescents, its impairment is similar across BD-I, II, and NOS, and with time, progressive numbers of BD-NOS participants develop more distinct episodes consistent with BD-I or II.

Another example of a longitudinal BD study is that conducted by Barbara Geller’s group at Washington University in St. Louis. Taken as a whole, her data align with that of the COBY study

in indicating that mania may start in childhood (mean age of onset = 7.4 ± 3.5) and that youth with BD suffer from recurrent manic and/or depressive symptoms. Specifically, a 4-year study of 86 children with DSM-IV bipolar I disorder (manic or mixed) with at least 1 cardinal symptom (elation and/or grandiosity) to ensure differentiation from ADHD showed that participants spent $56.9\% \pm 28.8\%$ of total weeks with mania or hypomania (unipolar or mixed), and $47.1\% \pm 30.4\%$ of total weeks with major or minor depression and dysthymia (unipolar or mixed) (Geller *et al.*, 2004b).

As described earlier (section “Differential Diagnosis”), Leibenluft *et al.* at NIMH also conducted a longitudinal study focusing on two groups of children: (i) “narrow-phenotype pediatric BD” (NP-BD) and (ii) SMD. Taken as a whole, data from over 150 NP-BD participants also shows that BD may start early in childhood and result in considerable impairment. Moreover, parents of NP-BD youths were significantly more likely to have BD themselves than were parents of SMD youths (Brotman *et al.*, 2007). Prospective data showed that only one of 84 SMD subjects (1.2%) experienced a (hypo)manic or mixed episode during a median 28.7 months of follow-up, whereas 58 of 93 NP-BD participants (62.4%) experienced such a (hypo)manic or mixed episode (Stringaris *et al.*, 2010b).

Summary

Longitudinal prospective studies are in early stages of seeing how BD youths develop into adults. Data suggest that episodic and chronic irritability in children predict different outcomes in adulthood, and that children with BD continue to experience considerable symptomatology and impairment.

Risk factors

Family studies

Those with a first-degree relative with BD are at an approximately 10-fold increased risk for BD, compared to those without such a history (Hodgins *et al.*, 2002; Smoller & Finn, 2003). The psychopathology among such at-risk children is of considerable interest. Six studies with $N > 50$ have assessed children of adults with BD (Grigoriu-Serbanescu *et al.*, 1989; Carlson & Weintraub, 1993; Chang *et al.*, 2000; Wals *et al.*, 2001; Henin *et al.*, 2005; Hillegers *et al.*, 2005). All find very high rates of psychopathology in these young people, with 44–63% meeting criteria for at least one DSM-IV-TR diagnosis, including ADHD, anxiety, MDD, and/or BD.

Twin and adoption studies

Twin studies suggest that the heritability of BD in adults is greater than 60%, with greater concordance for BD in monozygotic (60–70%) than dizygotic twins (20–30%) (Smoller & Finn, 2003).

With respect to gene/environment interactions and their relationship to the neural pathology of BD, Van der Schot *et al.*

found that genetic risk to develop BD was related to decreased gray matter density in the right medial frontal gyrus, precentral gyrus, and insula, and decreased white matter density in the superior longitudinal fasciculi ($N=232$ participants, including $N=49$ BD twin pairs – 16% monozygotic concordant, 31% monozygotic discordant, 8% dizygotic concordant, 45% dizygotic discordant) and $N=67$ healthy twin pairs (58% monozygotic, 42% dizygotic) (van der Schot *et al.*, 2010)).

Molecular genetic studies

The genetics of BD are complex and rapidly evolving, but several themes emerge. First, BD is due to multiple genes, not a single gene (Kelsoe, 2003). Second, the genes conferring risk for BD and those implicated in schizophrenia may overlap, as indicated by genome-wide association studies (GWAS) (Priebe *et al.*, 2012; Craddock & Sklar, 2013; Cross-Disorder Group of the Psychiatric Genomics Consortium *et al.*, 2013a, b). Third, many genes implicated in BD mediate cell signaling, including via calcium or cell growth, for example, brain-derived neurotrophic factor (BDNF) (Geller *et al.*, 2004a). Fourth, data implicating copy number variants (CNVs) are less robust than other disorders, such as autism.

Clinical prodromes/risk factors

Several longitudinal community-based studies have queried which childhood or adolescent diagnoses are associated with increased risk for later BD. A 10-year longitudinal study by Tijssen suggests that progression from symptoms of BD to full-blown BD was predicted by symptom persistence—that is, the longer symptoms exist, the more they progress (Tijssen *et al.*, 2010). Studies following depressed children into late adolescence or early adulthood find that prepubertal MDD is associated with increased risk for BD (Harrington *et al.*, 1990; Kovacs *et al.*, 1994; Rao *et al.*, 1995; Weissman *et al.*, 1999). However, the prevalence of BD ranged widely, perhaps because of small sample sizes or because of differences in patient characteristics (e.g., inpatients vs outpatients). Positive family history, psychosis, and rapid symptom onset may predict BD (Strober & Carlson, 1982; Geller *et al.*, 1994). COBY study data indicate that after 5 years of longitudinal follow-up, 45% (63/140) of BD-NOS patients had converted to either BD type I (32/63) or type II (31/63), with the strongest predictor of conversion being first- or second-degree family history of mania or hypomania (Axelson *et al.*, 2011). Clinic-based follow-up studies of children with ADHD do not consistently support an elevated risk for developing BD by adulthood (Mannuzza *et al.*, 1998; Hazell *et al.*, 2003).

Summary and conclusions

Although BD is clearly heritable, there is no single risk gene, nor is there a matrix of risk factors that is as yet clinically applicable. Ongoing and future work, directed at understanding the brain/behavior/gene interplay responsible for mania, depression, and euthymia, including work focused

on understanding full-blown categorical illness as well as the dimensional symptoms underlying these disorders, may prove more fruitful to identifying such biobehavioral markers of BD risk than BD itself as a categorical diagnosis.

Pathophysiology

Neural circuitry: computerized behavioral tasks and neuroimaging

Affective neuroscience—the study of brain/behavior interactions underlying emotion and neuropsychiatric disorders—has greatly advanced our pathophysiological understanding of BD in children and adolescents. With respect to structural magnetic resonance imaging (MRI), the most replicated finding in childhood-onset BD is significantly decreased amygdala volume, compared to controls (Blumberg *et al.*, 2003; DelBello *et al.*, 2004; Chang *et al.*, 2005; Dickstein *et al.*, 2005; Pfeifer *et al.*, 2008; Hajek *et al.*, 2009); data in BD adults are less consistent (Altshuler *et al.*, 1998). Ongoing work is evaluating potential development, gender, medication, and comorbidity effects on structural MRI alterations.

With respect to cognitive and emotional processes, using both out-of-scanner tasks and functional MRI (fMRI), studies have demonstrated that BD youths have aberrant functioning in at least four processes: emotional face processing, response inhibition, frustration, and cognitive flexibility.

Face processing deficits are perhaps the most robustly demonstrated alteration in BD youths. Specifically, BD youths make significantly more errors categorizing emotional faces than both typically developing children (TDC) without psychopathology and those with anxiety disorders (Guyer *et al.*, 2007) and youths with primary ADHD, especially on low-intensity happy faces (Seymour *et al.*, 2013). Similar deficits have been identified in youths at familial risk for BD (Brotman *et al.*, 2008). fMRI studies from several groups indicate that BD youths have abnormal prefrontal cortex (PFC)–amygdala–striatal neural activation compared with healthy subjects when viewing faces with happy, angry, or neutral emotions (Rich *et al.*, 2006; Pavuluri *et al.*, 2007; Kalmar *et al.*, 2009). Finally, studies suggest that different neural mechanisms mediate face processing deficits in children and adolescents with either BD or SMD (Rich *et al.*, 2008; Brotman *et al.*, 2010; Thomas *et al.*, 2013).

Response inhibition is linked to distractibility and impulsivity. Leibenluft *et al.* found that, compared to controls, BD youths had a reduced striatal “error signal” during failed motor inhibition (Leibenluft *et al.*, 2007), a deficit which might contribute to the patients’ inability to inhibit effectively. Another study found that BD youths had greater neural activation than TDCs in the right DLPFC during no-go versus go trials, suggesting greater reliance on cognitive control areas to maintain adequate behavioral performance (Singh *et al.*, 2010).

Tasks using rigged feedback to induce frustration are particularly relevant to advancing what is known about irritability in children and adolescents, given that irritability may be part of

both disorders. For example, Rich *et al.* found altered P3 EEG amplitude in BD versus both SMD and TDC participants using a task with rigged feedback, reflecting impairments in executive attention in the BD group. In contrast, regardless of condition, SMD youths had lower N1 amplitude than either BD or TDC participants, reflecting impairments in the initial stage of attention (Rich *et al.*, 2007). In a separate study using magnetoencephalography to identify aberrant brain activity during this frustration task, (after negative feedback,) BD participants had greater superior frontal gyrus activation and decreased insula activation than SMD and TDCs, while SMD participants had greater anterior cingulate cortex and medial frontal gyrus activation than TDCs (Rich *et al.*, 2011).

Cognitive flexibility—defined as the ability to adapt one's thinking and behavior in response to changing rewards and punishments—is relevant to BD because clinical features of BD may reflect specific alterations in how reward inaccurately shapes behavior—that is, hyper-hedonia in mania (e.g., excessive involvement in pleasurable activities with high potential for painful consequences) and hypo-hedonia in depression (e.g., anhedonia) (Cools *et al.*, 2002). Cognitive flexibility can be studied using reversal learning tasks. In these, subjects use trial-and-error learning to determine first, that an object is initially rewarded, and then, that this stimulus/reward relationship had switched, so that the previously rewarded object is now punished and vice versa. BD youths have impaired cognitive flexibility and reversal learning compared to TDC controls and SMD youths (Dickstein *et al.*, 2004; Gorrindo *et al.*, 2005; Dickstein *et al.*, 2007; Dickstein *et al.*, 2010a). fMRI studies have shown that BD youths had the opposite neural response as TDC participants during reversal learning (Dickstein *et al.*, 2010b).

Neurochemistry: magnetic resonance spectroscopy (MRS)

Magnetic resonance spectroscopy (MRS) research in BD has focused on *N*-acetyl aspartate (NAA), an intra-neuronal marker whose levels are decreased in neuropathology, and myo-inositol (mI), an intracellular second messenger, thought to be overabundant in mania, whose levels are decreased by lithium (Moore *et al.*, 1999; Silverstone *et al.*, 2002).

Youth with familial BD (Chang *et al.*, 2003), and adults with BD (Winsberg *et al.*, 2000), have significantly decreased NAA in the dorsolateral PFC compared to controls. Studies also indicate that BD youths have increased ACC mI compared to healthy controls or youth with intermittent explosive disorder (Davanzo *et al.*, 2003), with mI levels being responsive to lithium treatment (Davanzo *et al.*, 2001). Together, these MRS studies suggest that BD youths may be characterized by specific neurochemical alterations that respond to psychopharmacological treatment; future work in this area may ultimately inform such treatment.

Diffusion tensor imaging (DTI)

Diffusion tensor imaging (DTI) studies have shown disrupted white matter integrity in tracts connecting the PFC as indexed

by decreased fractional anisotropy (FA) among BD versus TDC youths (Adler *et al.*, 2006). Children with BD and those at risk for BD by virtue of having a first-degree relative with BD had decreased FA versus controls in the superior longitudinal fasciculus bilaterally, suggesting that this might be a trait marker of BD (Frazier *et al.*, 2007). However, others have suggested that these changes might not be specific to BD, as similar alterations have been shown in youths with primary ADHD (Pavuluri *et al.*, 2009).

Summary

In sum, research has demonstrated brain/behavior alterations in children and adolescents with BD, including structural and functional alterations in fronto-temporo-striatal circuits mediating behaviors such as face processing, response inhibition, response to frustration, and cognitive flexibility. Ongoing work is needed to determine the specificity of these brain and behavior alterations, and thus identify if they are useful targets for diagnostic biomarkers or for novel treatments or treatment monitoring.

Treatment

General approach

The past decade has witnessed the publication of several double-blind randomized placebo-controlled trials (RCTs) for antimanic agents in children and adolescents. Current data preclude designating any psychopharmacologic or psychotherapeutic treatment as having “strong” evidentiary support. Given the paucity of pediatric data, clinicians often rely on data from adult BD despite ongoing controversy about phenomenological differences in children with BD versus adults with BD. Hence, where appropriate, we summarize briefly the most relevant adult data. Nevertheless, caution is urged in basing treatment on adult data, since youth may respond differently than adults, as in major depression.

Clinicians should focus treatment on the most acute and disabling aspects of BD—for example, acute mania, depression, psychosis, substance abuse, and suicidality (Figure 62.1). Later treatment addresses other problems—for example, comorbid anxiety, ADHD, substance abuse, and deficient social skills. Treatment decisions require collaboration among physicians, patients, and families to identify target symptoms, educate about side effects, and evaluate each treatment's efficacy. Daily ratings of target symptoms by parents and/or patients allow treatment to be based upon prospective, rather than retrospective, data. Moreover, patient safety, including functional impairment, suicidal thoughts, and treatment-emergent side effects, must be evaluated continuously. This includes considerations of level of care required to manage the patient safely, though there are no universal standards for inpatient versus outpatient care.

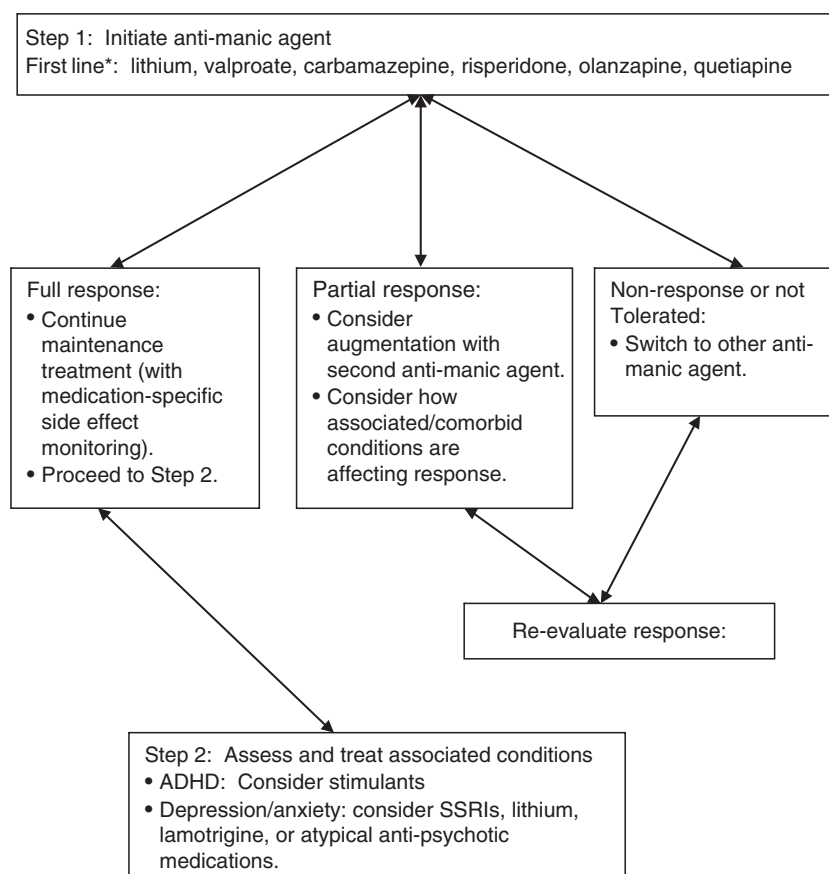

Figure 62.1 Psychopharmacology algorithm. *First-line agents based upon present data in childhood-onset BD. *Source:* Modified from/see also: Kowatch *et al.* (2005).

Furthermore, clinicians must consider common issues affecting children and adolescents, including substance use and pregnancy. Most antimanic and antidepressant agents are metabolized by the liver. Thus, any other medication or drug of abuse also metabolized by the liver, including alcohol, may influence treatment response and side effect risk. Regarding pregnancy, certain antimanic agents, including antiepileptic drugs (e.g., valproate) and lithium, have known adverse effects on the developing fetus. Thus, clinicians must discuss these risks with their patients, as well as potential alternatives to medication and the need for contraception.

Ideally, medication trials should last at least 6–8 weeks, with one new agent added at a time. However, this approach may not be feasible in acutely manic or psychotic patients. Physicians should assess continuously the need for each medication to determine whether any can be discontinued. Moreover, symptoms do not typically resolve on medication alone; rather, comprehensive treatment usually requires both psychopharmacology and psychotherapy. Finally, treatment must address the phase of a child's illness, since acute and maintenance interventions differ.

Psychopharmacology for pediatric bipolar disorder

Pharmacotherapy of mania

Currently available antimanic medications intended to reduce symptoms of, and to prevent the occurrence of, hypo/mania include: (i) lithium, (ii) second-generation antipsychotic medications (SGAs), and (iii) antiepileptic medications (AEDs, for example, valproate and carbamazepine) (see Figure 62.1). Recent RCTs support the following conclusions: (i) SGAs are effective, and potentially superior to other antimanic agents, in the treatment of BD. However, such medications are associated with significant side effects, most notably impairing weight gain and metabolic abnormalities; (ii) lithium's role in BD children is less clear than in BD adults, though further study is warranted, given studies showing its efficacy in pediatric patients with extreme aggression; and (iii) AEDs may be less efficacious than other antimanic agents for children with BD. The lack of a "silver bullet" or single best antimanic agent complicates efforts to select any one agent as a first-line treatment and again emphasizes the importance of thorough discussions with patients and their families. For an individual, a step-wise

approach is often needed, involving trying different antimanic agents if initial attempts are unsuccessful. The treatment of acute mania may require augmentation with anxiolytic medications short-term. We focus our discussion on efficacy and the most important side effects, but for dosing guidelines and a more thorough discussion of side effects, see Kowatch *et al.* (2005), Correll *et al.* (2006).

Second-generation antipsychotic medications (SGAs)

SGAs have the strongest efficacy data in BD youths; however, there are concerns about side effects, such as substantial weight gain and metabolic syndrome, and about potential over prescription to children in general (Andrade *et al.*, 2011). Risperidone, aripiprazole, and quetiapine have FDA indications to treat mania or mixed states associated with BD in 10–17-year-olds.

Aripiprazole was evaluated in a 4-week double-blind placebo-controlled RCT of $N=296$ 10–17-year-olds currently in a mixed or manic episode. At either 10 mg/day or 30 mg/day, aripiprazole was better than placebo in reducing manic symptoms (Findling *et al.*, 2009). A second study found that after 16 weeks of open treatment, 4–9-year-olds with BD ($N=96$) randomized to remain on aripiprazole were more likely to remain without a mood episode versus those switched to placebo ($N=30$ per group; weeks without mood episode 6.14 ± 11.8 on aripiprazole, 2.29 ± 0.38 on placebo) (Findling *et al.*, 2012).

Studies of risperidone include a study of 10–17-year-olds with BD type I currently manic or mixed randomized to receive risperidone 0.5–2.5 mg/day ($N=50$), 3–6 mg/day ($N=61$), or placebo ($N=58$) for 3 weeks. Both risperidone groups showed significant reductions in mania compared to placebo (Haas *et al.*, 2009). Other studies have compared the clinical and neural outcome of BD youths treated with risperidone versus divalproex (Depakote), showed that neither treatment was clearly superior, although this may have been a type II error, given small sample size ($N=24$ total). They did find that risperidone may have reduced mania faster (Pavuluri *et al.*, 2011a).

A particular concern is the association of SGA with “metabolic syndrome”—that is, extreme and rapid weight gain and endocrine abnormalities, including diabetes mellitus. A study of $N=338$ children aged 4–19 years treated for a median of 10.8 weeks with SGAs, showed that weight increased by a mean of 8.5 kg for olanzapine, 6.1 kg with quetiapine, 5.3 kg with risperidone, and 4.4 kg with aripiprazole, versus 0.2 kg in an untreated group. Increases were also noted in total cholesterol, triglycerides, and nonhigh-density lipoprotein (Correll *et al.*, 2009). Children treated with SGAs have a greater risk of developing diabetes (3.23/1000) than those receiving antidepressants (1.86/1000) or no treatment (0.76/1000) (Andrade *et al.*, 2011). Patients should be monitored routinely for weight, height, and body mass index, and fasting glucose and lipid panel every 6 months. Finally, for SGAs, firm conclusions on the risk of tardive

dyskinesia are not possible because of the lack of long-term data (Ghaemi *et al.*, 2006).

Lithium

Support for lithium's efficacy in childhood-onset BD is mixed. Efficacy and safety data place it in the middle of the three categories of medications typically used in childhood-onset BD—ahead of AEDs but weaker than SGAs. Moreover, lithium has an FDA indication for the treatment of mania in patients as young as 12 years, but it was “grandfathered” in and would not be granted on the basis of current standards. Nevertheless, in BD adults, there is robust evidence for lithium's efficacy in adult acute mania (Bowden *et al.*, 2005), long-term prophylaxis (Bowden *et al.*, 2003), and reduction of suicide risk (Cipriani *et al.*, 2005). Thus, it may be reasonable to prescribe lithium for individual BD youths, especially those who do not respond to SGAs.

The largest and most recent data set about lithium comes from the Treatment of Early Age Mania (TEAM) study of $N=279$ children aged 6–15 years with type I BD randomized to receive 8 weeks of either lithium, risperidone, or divalproex sodium. Lithium was not significantly better in treating mania than divalproex, and resulted in higher discontinuation rate than risperidone (Geller *et al.*, 2012). However, one wonders if atypical features of this sample may reduce its generalizability to typical childhood-onset BD cases. Specifically, the average age of mania onset was 5.2 ± 2.6 years, and their average mania duration 4 years—translating into the fact that most were in a continuous state of a manic or mixed episode. Another RCT study failed to find a significant difference between adolescents ($N=108$) whose acute mania was initially stabilized with open lithium treatment, and who were then randomized to either continue lithium or switch to placebo during a double-blind discontinuation study (Kafantaris *et al.*, 2004).

Adult studies suggest that optimal lithium levels are between 0.6 and 1.0 mEq/l for acute mania and down to 0.4 mEq/s for maintenance treatment, but this has not been tested rigorously in youth (Gelenberg *et al.*, 1989). Of note, an MRS study showed that BD youth ($N=9$) had lower brain/serum lithium concentrations than BD adults ($N=18$) (Moore *et al.*, 2002), suggesting that BD youths may require higher doses of lithium to achieve the same brain concentration of lithium as adults. However, the clinical implications of this finding have not been studied systematically.

Antiepileptic drugs (AEDs)

Relative to lithium or SGAs, support for the therapeutic efficacy of the AEDs in childhood-onset BD is weakest. However, safety data for AEDs (largely gleaned from studies of pediatric epilepsy) is generally strong, with the exception of questions regarding acute hepatic or pancreatic failure and possible adverse effects on female gonadal function (see below) (de Silva *et al.*, 1996).

Data from two RCTs fail to demonstrate the benefits of AEDs in childhood-onset BD (Wagner *et al.*, 2006, 2009). While open-label trials, most of them small, document some evidence of benefit for carbamazepine, valproate, or lamotrigine, in the absence of a placebo control these studies can provide only weak support for efficacy (Wagner *et al.*, 2002; Chang *et al.*, 2006).

Adult studies of AEDs have shown efficacy for acute and maintenance antimanic treatment in adults, leading to FDA indications for both valproate and a long-acting form of carbamazepine, (Pope *et al.*, 1991). Lamotrigine is another AED with an FDA indication for BD in adults, although data suggest that it is more effective as a maintenance treatment, preventing depressive and manic relapse, than for acute mania (Bowden *et al.*, 2003).

Valproate has a black-box FDA warning due to the possibility of acute, life-threatening hepatic failure and pancreatitis, both of which are more common in those on multiple medications or less than 2 years old (Grauso-Eby *et al.*, 2003). Therefore, any patient taking valproate who develops the acute onset of nausea, vomiting, or acute abdominal pain should receive prompt medical evaluation. Also, irregular menses and polycystic ovary syndrome (PCOS; i.e., polycystic ovarian morphology, increased serum testosterone or luteinizing hormone, and irregular menses) may be associated with valproate use, particularly in young women (McIntyre *et al.*, 2003).

Lamotrigine also has an FDA black-box warning for children younger than 16 due to potential for two different life-threatening rashes, Stephens-Johnson syndrome and toxic epidermal necrolysis. More benign rashes are common, and a meta-analysis found that increased risk for such rashes was associated with patient age less than 12 years or coadministration of medications that inhibit hepatic metabolism (e.g., valproate) (Calabrese *et al.*, 2002).

Pharmacotherapy of depression in childhood-onset BD

The lack of RCT data to guide medication treatment of depression or anxiety in BD youths is problematic. Data suggest that (i) BD youths spend a considerable amount of time struggling with depression and/or anxiety; (ii) BD youths often receive SSRIs to augment their antimanic treatment without the induction of mania; (iii) there is some suggestion that the risk of antidepressant-induced mania is higher in prepubertal children than in older adolescents or adults (Martin *et al.*, 2004), and (iv) in adult BD, it is unclear whether SSRI antidepressants or lithium are preferable in the treatment of adult bipolar depression (Thase, 2007). Specifically Martin *et al.* used nationally representative pharmacy data to show that among 87,920 5–29-year-olds, 5.4% ($N=4781$) experienced manic conversion during a median of 41 weeks of follow-up. This was more common in prepubertal children than older adolescents or adults (number needed to harm [NNH] = 10 10–14-year olds vs 23 in 15–29-year-olds) and also more common after exposure to tricyclic antidepressants than SSRIs.

In BD adults with depression, RCTs demonstrate efficacy for lamotrigine, quetiapine, and the combination of olanzapine plus fluoxetine (Calabrese *et al.*, 2005; Tohen *et al.*, 2005).

Pharmacotherapy of ADHD in childhood-onset BD

There is a similar lack of evidence-based guidance to treat ADHD among children with BD. Although concerns have been raised about the possibility of ADHD-medication-induced mania, large numbers of phenomenology studies show that these agents are commonly used without such exacerbation (Carlson *et al.*, 2000). One double-blind crossover RCT in children with childhood-onset BD and ADHD found that, once mania remitted on valproate, amphetamine salts plus valproate was more effective in reducing ADHD symptoms than placebo plus valproate, without exacerbating mania ($N=30$) (Scheffer *et al.*, 2005). Thus, clinicians treating youth with BD and comorbid ADHD should treat the patient's mania, and then consider psychostimulant treatment.

Psychotherapy for pediatric bipolar disorder

When combined with pharmacotherapy, several types of psychotherapy show promise in treating childhood-onset BD. Family-focused psychoeducational therapy (FFT) includes psycho education, communication enhancement, and problem-solving skills. When administered for 21 sessions over 9 months to BD youths after an index mood episode, FFT resulted in faster recovery and fewer weeks depressed versus those randomized to receive only three family sessions focused on relapse prevention. However, there was no significant difference in rates of recovery from mania or time to recurrence of mania or depression (Miklowitz *et al.*, 2008). Multifamily psychoeducational groups are designed to increase parents' knowledge about BD and ability to obtain services. Multifamily psychoeducational groups administered in eight 90-min sessions have shown greater reduction in the mood severity index, a combination of the Young mania rating scale and Children's Depression Rating Scale, than those receiving a wait-list control (Fristad *et al.*, 2009). Cognitive behavioral therapy (CBT) with family involvement was associated with significant symptom reduction in an open trial of $N=34$ BD youths (Pavuluri *et al.*, 2004). More RCTs are needed to document efficacy and of head-to-head comparisons.

Summary

The treatment of childhood-onset BD requires a comprehensive approach to meet the complex needs of the disorder, with targeted pharmacotherapy and psychotherapy. Ongoing work is evaluating the neural mechanism and outcome of treatment. Important unknowns requiring additional study include (i) how to address anxiety, ADHD, and depression associated with BD; (ii) which agent to use for a particular patient; and (iii) what are the moderators/mediators of treatment response?

Future developments and necessary research

Hopefully, the future will bring greater pathophysiological understanding of childhood-onset BD. New diagnostic criteria in DSM-5 will undoubtedly shape clinical and research work on mood and behavioral disorders in children, including BD and DMDD. Additional advances are likely to come from (i) longitudinal studies of BD youths now becoming young adults and (ii) novel treatments.

Longitudinal studies come of age

Several studies have continued to prospectively follow these participants who are coming of age—entering young adulthood. These longitudinal studies are crucial in understanding what happens to these BD youths when they grow up to answer questions such as: How does the phenomenology of their illness change (duration and frequency of episodes; identifying risks for developing manic and depressive episodes)? What will their pattern of healthcare utilization be (treatment seeking, settings, and costs of care)? How will the brain/behavior interactions underlying BD change as these children with BD become adults with BD?

Novel treatments

Some have expressed concern about the future of novel medication treatments for neuropsychiatric disorders, including BD, given pharmaceutical industry reports about the dearth of novel compounds in the pipeline to be available clinically, reduction of number of companies providing such agents, or reduction in funding mechanisms available to study such agents. However, the future may not be so bleak, as novel approaches, including pharmacoinaging or pharmacogenomics (Pavuluri *et al.*, 2011b), result in a more personalized treatment approach, as an individual's biology is factored into determinations of what treatment is most likely to result in improvement, or least likely to result in side effects, akin to what is currently done in treating cancer, although this is clearly a long way off.

The future will likely require such a union of affective neuroscience techniques and treatment studies. Beyond traditional treatment targets of mania and depression, enhancing cognitive function via nonpharmacological options is an important target for interventions research, given that cognitive impairments in those with psychopathology are strongly linked to functioning at school, work, home, and social relationships (Martinez-Aran *et al.*, 2004). This approach, known as cognitive remediation, has shown great promise in adults with disorders, including schizophrenia (McGurk *et al.*, 2007), and in children with ADHD (Shalev *et al.*, 2007).

In sum, while much is known about BD in children and adolescents, there is ample work for the current and future generations of child mental health clinicians and researchers.

Depressive disorders in childhood and adolescence

David Brent¹ and Fadi Maalouf²

¹Child and Adolescent Psychiatry, Western Psychiatric Institute, University of Pittsburgh, PA, USA

²Child and Adolescent Psychiatry Program, Department of Psychiatry, American University of Beirut, Lebanon

Clinical picture

Phenomenology and classification

Depressive disorders are all characterized by persistent, impairing sadness, anhedonia, or irritability that is relatively unresponsive to pleasurable activities and interactions, and attention from other people.

Depressive disorders are classified on the basis of severity, chronicity, presence of mania, and seasonality. To qualify, according to DSM-5, the patient must experience functional impairment related to a change in mood. This mood change cannot better be explained by another condition, for example, medical disorder or substance abuse. ICD-10 does not formally require functional impairment, but describes it as a frequent accompaniment of depression based on severity (World Health Organization, 2010). In DSM-5, major depressive disorder is characterized by at least 2 weeks of persistent change in mood, nearly every day, manifested by either depressed or irritable mood, or loss of interest or pleasure and at least four additional symptoms of depression: changes in appetite or weight, sleep, psychomotor activity, decreased energy, feelings of worthlessness or guilt, difficulty thinking or concentrating, or recurrent thoughts of death or suicidal ideation, plans, or attempts. Chronic depression involves depressive symptomatology that lasts for at least 12 months. Other specified depressive disorder is used for patients whose depressive symptoms are impairing but do not meet duration or number of symptom requirements, such as those with brief recurrent depression, with recurrent symptoms of duration shorter than 2 weeks, or a longer depressive episode that is impairing with fewer than the required number of symptoms for major depressive disorder.

Changes from DSM-IV to DSM-5

Dysthymic disorder, a chronic and intermittent depressive disorder lasting at least 1 year, is now subsumed under persistent depressive disorder.

A newly introduced condition, “disruptive mood dysregulation disorder” (DMDD), is characterized by severe persistent irritability with temper outbursts occurring at least three times weekly in youth at least aged 6 and with onset prior to age 10 (American Psychiatric Association, 2013). DMDD shows extremely high diagnostic overlap with oppositional and mood disorders, and further research is required to clarify if DMDD is distinct from its commonly co-occurring, related conditions (Axelson, 2013; Copeland *et al.*, 2013); see Chapter 62.

The bereavement exclusion for major depression has been dropped, meaning that bereaved patients who meet criteria for major depression within the first 2 months of a loss can be diagnosed accordingly. This change is consistent with findings that the phenomenology, course, and risk factors for depression associated with bereavement are similar to those whose depression is unrelated to bereavement and that the highest risk period for bereaved individuals to become depressed is immediately after the loss (Bridge *et al.*, 2003; Hamdan *et al.*, 2012).

Differential diagnosis

The most important differential diagnosis is between unipolar and bipolar depression. However, manic symptoms do not necessarily mean that the patient has bipolar disorder, as only 25% of youth with clinically significant mania in one clinical epidemiological study meet criteria for bipolar spectrum disorder (Findling *et al.*, 2010). Depression may also present with psychotic features, typically of depressive, self-deprecatory, or paranoid content. With regard to the latter, the main differential is between prodromal symptoms of schizophrenia, and can often only be determined through longitudinal follow-up. Major depression that occurs in the fall and remits in the spring, characterized by hypersomnia, fatigue, and carbohydrate craving is categorized as seasonal affective disorder.

Anxiety disorders are often associated with significant dysphoria that is relieved if the anxiogenic situation (e.g., separation, social situations) is eliminated. The social withdrawal of depression should be differentiated from social avoidance due to anxiety.

Altered concentration is not only a symptom of depression, but is a key feature of attention deficit hyperactivity disorder (ADHD). ADHD usually has an earlier onset than depression and is often associated with impulsivity and hyperactivity. Children with ADHD frequently become demoralized due to peer rejection and difficulties at school, but in contrast to depression, the symptomatic presentation of ADHD (e.g., inattention) does not become worse with changes in mood.

Irritability is a prominent symptom of conduct (CD) and oppositional defiant disorder (ODD). In the absence of other mood symptoms, irritability is more likely to be due to the behavioral disorder than depression. However, high levels of irritability in childhood predict depression and anxiety in adulthood (Stringaris *et al.*, 2009; see Chapter 5).

Substance abuse can mimic mood disorders by disrupting sleep, concentration, motivation, and appetite; moreover these conditions frequently co-occur with mood disorders in clinical practice. A careful history and, when warranted, a drug toxicology screen can help detect this important and serious condition.

Patients with eating disorders often show lassitude and dysphoria, which can in part be attributed to poor nutritional status. A diagnosis of current depression in an eating disordered patient should not be made until adequate nutritional status has been restored.

Some medical conditions (e.g., hypothyroidism, mononucleosis, anemia, sleep apnea) may mimic depressive symptoms, particularly fatigue, low energy, and low motivation.

Comorbidity

Between 40% and 90% of youth with depressive disorders also have other psychiatric disorders (Angold *et al.*, 1999). Comorbidity may result from shared etiology, or as a cause or consequence of depression. Anxiety is frequently a precursor of, and shares a genetic diathesis with, depression (Middeldorp *et al.*, 2005). ADHD and depression are also often comorbid, but attentional symptoms should only be counted toward depression if they worsen in association with changes in mood. Comorbidity between depression and behavioral disorders and substance abuse may be attributable to shared family risk factors, such as abuse, exposure to family violence and discord, and parental substance abuse (Harrington, 2000). ODD may predispose to depression via difficulty with emotion regulation and tendency to negative affectivity (Hipwell *et al.*, 2011; Burke, 2012). Longitudinal studies suggest that while the relationship between depression and substance abuse is bidirectional, substance abuse is more likely to lead to depression than *vice versa* (Boden & Fergusson, 2011; Horwood *et al.*, 2012).

Assessment

Self- and parent-report questionnaires are useful for screening for depression and monitoring treatment response and are time-efficient. The Mood and Feelings Questionnaire (MFQ) is the only self- and parent-reported scale validated for both children and adolescents and comes in a 37-item and 13-item form, the latter of which is useful for screening for depression (Wood *et al.*, 1995; Thapar & McGuffin, 1998). The Children's Depression Inventory (CDI) was developed as a downward extension of the Beck Depression Inventory (BDI), has self-, parent-, and teacher-report forms, is highly correlated with other measures of depression, and discriminates depression from anxiety and disruptive disorders (Timbremont *et al.*, 2004). The Patient Health Questionnaire-2, consisting of two items (low mood and anhedonia) has been validated as a screen for depression in adolescents, as has the longer nine-item version (Richardson *et al.*, 2010). Three other measures with good psychometric properties that have been used to screen for depression and to monitor treatment effects are the Center for Epidemiologic Studies-Depression Scale (CES-D; although it lacks a suicide ideation item), the BDI, and the Reynolds Adolescent Depression Scale (RADS-2). In a comparison of the CES-D and BDI using item-response theory, the CES-D performed better in lower ranges of symptomatology, whereas the BDI performed better at higher ranges of symptomatology (Olino *et al.*, 2012). A newly developed eight-item self-report, the Patient Reported Outcome Management Information System (PROMIS), showed better performance than either the CES-D or the BDI over the full range of symptomatology, although it has not been used in treatment studies (Olino *et al.*, 2013). The RADS-2 shows strong psychometric properties, including treatment sensitivity (March *et al.*, 2004; Osman *et al.*, 2010). The Preschool Feelings Checklist is one parent-report instrument validated for preschool depression (Luby *et al.*, 2004).

Interview-rated assessments, while more labor-intensive, can integrate reports from parents and youth, and permit the ascertainment of the temporal sequence, course, and functional significance of different symptoms. The interviewer can determine the extent to which a specific symptom should be attributed to the diagnosis of depression in the face of comorbidity (e.g., if a patient has preexisting ADHD, to determine if concentration problems should be attributed to depression) (see also Chapter 32). The most common interview used in research studies in child and adolescent depression is the semistructured Schedule for Affective Disorders and Schizophrenia for School-Age Children-Present and Lifetime version (K-SADS-PL) (Kaufman *et al.*, 1997). Several other instruments have good psychometric properties, and may be more appropriate for epidemiological studies, because they are either briefer or fully structured.

The most commonly used continuous, interview-based measure of depressive symptomatology is the Children's Depression Rating Scale-Revised (CDRS-R), a 17-item assessment that has

been shown to have good reliability and treatment sensitivity (Mayes *et al.*, 2010).

Descriptive epidemiology

Prevalence

The point prevalence of depressive disorders is 1–2% in preschool and older prepubertal children and 3–8% in adolescents, with the lifetime prevalence by the end of adolescence of around 20% (Lewinsohn *et al.*, 1998; Costello *et al.*, 2003). One-year and 1-month prevalence estimates of major depressive disorder in adolescents in the National Comorbidity Survey Replication are 8.2% and 2.6%, respectively (Kessler *et al.*, 2012). Studies conducted in countries of lower or middle income report higher point prevalences of clinically significant depressive symptomatology (10–13% in boys and 12–18% for girls) (Ruchkin *et al.*, 2006; Alyahri & Goodman, 2008).

Age, gender, and puberty

The dramatic female predominance in depression that first emerges with puberty may be mediated by increases in estradiol and testosterone (Angold *et al.*, 1998). Adolescent-onset depressive disorder has a higher risk of recurrent mood disorder into adulthood as compared to depression of prepubertal onset, and shows a greater degree of heritability (Shanahan *et al.*, 2011). Earlier onset of puberty may increase the risk of depression in girls, perhaps mediated by an increased risk of conduct disorder. The dramatic neurodevelopmental remodeling of prefrontal and limbic structures involved in social attribution, emotion regulation, and reward response that occurs in adolescence may contribute to increased vulnerability to depression, as well as increased rates of sleep disruption, and alcohol and drug use (Hayward *et al.*, 1997; Dahl, 2004; Andersen & Teicher, 2008; Boden & Fergusson, 2011; Casey *et al.*, 2011; Shanahan *et al.*, 2011; Horwood *et al.*, 2012).

Course and outcome

Episode length and recovery

The duration for depressive episodes ranges between 3 and 6 months for community samples, and between 5 and 8 months for referred samples (Birmaher *et al.*, 2002), with around 1 in 5 depressed adolescents showing evidence of depression of duration two years or greater (Lewinsohn *et al.*, 1998; Birmaher *et al.*, 2000).

Risk for recurrence

The risk for recurrent depression after an initial episode ranges from 30% to 70% within the first 2 years, and is higher in those with chronic depression, subsyndromal symptoms, comorbidity, and family conflict (Birmaher *et al.*, 2002; Emslie *et al.*, 2008). The continuity between adolescent and adult depression may be

partly mediated by comorbid ODD, anxiety, and substance abuse (Copeland *et al.*, 2009).

Bipolar disorder

The risk of bipolar disorder in early-onset depression is estimated to be around 10–20% (Geller *et al.*, 2001), with elevated risk in patients who present with hypomania in response to treatment, psychotic features, hypersomnia (in some studies), and a family history of bipolar disorder (Strober & Carlson, 1982; Geller *et al.*, 2001).

Suicidal behavior and health risk behaviors

Suicidal behavior is a common sequela of early onset depression, and the mortality due to suicide is elevated at least 10-fold compared to nondepressed youth (Bridge *et al.*, 2006). Risk factors for suicidal behavior among depressed youth include greater severity and chronicity of depression, current ideation with a plan or a history of a suicide attempt, a history of nonsuicidal self-injury, insomnia, comorbid anxiety, conduct or substance abuse disorders, high levels of impulsive aggression, greater hopelessness, family history of suicidal behavior, abuse, family conflict, and lack of support (Bridge *et al.*, 2006; Wilkinson *et al.*, 2011; Nock *et al.*, 2013). Depression is associated with multiple health risk behaviors, including obesity (Hasler *et al.*, 2005; Katon *et al.*, 2010), and like suicidal behavior, predisposing factors to health risk behaviors include continued depression, comorbidity, low connection with parents, family discord, and history of abuse (Fergusson & Woodward, 2002; Lewinsohn *et al.*, 2003; Shanahan *et al.*, 2011).

Models of depression

We employ a stress-diathesis perspective for this review of risk factors for depression, that is, depression is most likely to develop in those with a vulnerability—defined by family history, cognitive bias, emotion dysregulation, fearfulness, or irritability, in concert with the experience of stressors—such as family conflict, child maltreatment, or peer victimization (Wilkinson & Goodyer, 2011).

Vulnerability factors for depression

Genetic

Twin studies demonstrate that depressive symptoms have a greater concordance among monozygotic than among dizygotic twins, with a heritability of around 40%, that vulnerability to depression may be cotransmitted with anxiety, and that adolescent-onset depression is more heritable than preadolescent onset depression (Thapar & Rice, 2006). In addition, a number of characteristics that predispose to depression, such as cognitive bias and difficulty with emotion regulation, appear to be familially transmitted (Su *et al.*, 2010; Owens *et al.*, 2012).

“Top-down” studies show a two- to fourfold increased risk of depressive disorder in the offspring of depressed parents

(Weissman, 2006). Greater family loading, such as depression in two generations and increased rates of parental and child anxiety disorders, were associated with an increased risk and earlier onset of depression (Weissman, 2006).

A mega-analysis of genome-wide association studies, comprising 9420 major depression cases and 18,759 controls, found no association between any gene and major depression, but did find 15 single-nucleotide polymorphisms (SNPs) associated with either major depression or bipolar disorder, all located in a 248 kb interval 3p21.1 (Ripke *et al.*, 2013).

The most frequently reported candidate gene variant associated with depression is a less functional allelic variant of the serotonin transporter gene (5HTTLPR), which is associated with early-onset depression, in the presence of stressful life events, a history of abuse, or peer victimization (Caspi *et al.*, 2010). However, the strength and consistency of these findings has been variable (see Chapter 24; Risch *et al.*, 2009). This genetic variant has been shown to be related to biological correlates of depression and anxiety, namely, negative information processing bias (Owens *et al.*, 2012), hypersecretion of cortisol in response to a social stressor (Gotlib *et al.*, 2008), and increased amygdala reactivity to emotional faces (Hariri *et al.*, 2002).

Cognitive distortion and rumination

The cognitive theory for depression is that depression is caused by biased attention to negative emotional cues, thereby reinforcing depressive symptomatology. Individuals with a negative inferential style are more likely to show growth in depressive symptoms; moreover, there is a bidirectional relationship in which cognitive distortions lead to stress generation, which in turn fuels growth in cognitive distortion over time (Gotlib & Joormann, 2010; Hankin, 2012). Rumination, or the tendency to dwell excessively on emotionally upsetting material, predicts the onset and growth of depressive symptomatology and is more prominent as a risk factor in girls (Hankin, 2012).

Emotion regulation

Emotion regulation, which is the ability to achieve emotional equilibrium in the face of perturbation, has been hypothesized to be a core deficit predisposing to depression (Kovacs & Lopez-Duran, 2010). Consistent with the cognitive theory of depression, individuals with emotion regulation difficulties are less able to shift attention away from negative emotion-laden, ruminative cognitions. Both self-report and laboratory assessment of emotion regulation (e.g., persistence in the face of frustration, decreased heart rate variability) are related to growth in children's internalizing and depressive symptoms (Kovacs & Lopez-Duran, 2010).

Fear and anxiety

Both fearfulness and anxiety disorders *per se*, especially social anxiety, are associated with an increased risk of depression, consistent with a shared genetic diathesis between anxiety and

depression (Pine *et al.*, 1998, 2001; Middeldorp *et al.*, 2005; Beesdo *et al.*, 2007).

Behavioral disorders and irritability

The rates of depression are increased both in patients with attention deficit disorder hyperactivity (ADHD) and their parents (Faraone & Biederman, 1997). Depression may ensue as a consequence of rejection from peers, teachers, and parents, and due to poor emotion regulation characteristic of ADHD (Seymour *et al.*, 2012). The relationship between ODD and depression may be mediated by the dimension of ODD associated with negative affect and irritability, whereas the link between CD and depression may be because CD results in the generation of stressful life events (e.g., arrests) that may be depressogenic (Fergusson *et al.*, 2003; Stringaris *et al.*, 2009; Hipwell *et al.*, 2011; Burke, 2012).

Sleep

Subjective sleep complaints are a more prominent component of early-onset depression than objective findings (Forbes & Dahl, 2012). However, decreased REM latency, increased REM density, and decreased sleep efficiency have been reported to be associated with depressive onset, recurrence, and persistence in some studies (Rao *et al.*, 2009). Insomnia has been shown to have a bidirectional relationship with the onset and growth of depressive symptoms (Gregory *et al.*, 2009; Cousins *et al.*, 2011). In specific, sleep deprivation results in increased mood lability and greater attention to negative emotional cues (Soffer-Dudek *et al.*, 2011; Dagys *et al.*, 2012).

Comorbid medical illness

Poor physical health is associated with adolescent depression, in part due to interference with activities that are enjoyable or enhance a sense of mastery (Lewinsohn *et al.*, 1998). There are also systemic effects of chronic illness, particularly those that involve the central nervous system (e.g., epilepsy, migraine) or that affect the inflammatory system (e.g., inflammatory bowel disease, asthma), as well as depressogenic effects from some of the treatments (e.g., corticosteroids, interferon) (Lewinsohn *et al.*, 1998; Szigethy *et al.*, 2010; Hoppe & Elger, 2011; Bruti *et al.*, 2012; Goodwin *et al.*, 2012).

Environmental risk factors

Parental depression and family discord

Adoption studies show that maternal depression is not only a genetic, but also an environmental risk factor for both externalizing disorders, and for depression (Tully *et al.*, 2008). Conversely, treatment of maternal depression can result in symptomatic improvement in youth, in both externalizing and internalizing symptoms (Brent *et al.*, 1998; Gunlicks & Weissman, 2008; Swartz *et al.*, 2008). The impact of maternal depression may be mediated by family discord and expressed emotion directed toward the child, which in turn predicts onset, persistence, and recurrence in at-risk subjects (Silk *et al.*, 2009).

Child maltreatment

Physical or sexual abuse, neglect, and exposure to domestic violence are potent risk factors for the onset and recurrence of depression. Abuse may be more likely to lead to depression in those at increased genetic risk (e.g., family history of depression) (Kaufman *et al.*, 2006; Caspi *et al.*, 2010).

Peer victimization

Both bullies and their victims have higher rates of depression than controls (Zwierzynska *et al.*, 2013). Peer victimization can have long-lasting effects on increasing depressive symptomatology, may be mediated by increasing negative cognitions and may be more common in those with a high cortisol response to a laboratory-based social stressor (Rudolph *et al.*, 2011; Sinclair *et al.*, 2012; Zwierzynska *et al.*, 2013).

Sexual minority status

Sexual minority youth (i.e., lesbian, gay, bisexual, or transgendered) are about three times more likely to have depression as heterosexual youth, and these effects appear to be mediated by peer victimization (Marshall *et al.*, 2011; Burton *et al.*, 2013), and may also be accounted for by parental rejection, assault, and higher rates of abuse (Friedman *et al.*, 2011).

Bereavement

Parental or peer bereavement is associated with a threefold increased risk for depression even after controlling for other preexisting risk factors, and appears phenomenologically similar to nonbereavement-related depression (Bridge *et al.*, 2003; Hamdan *et al.*, 2012). The increased risk is greatest immediately after the death, and is more likely in those with a previous history of depression, who lost a close friend rather than an acquaintance, and who lost a mother rather than father (Bridge *et al.*, 2003; Brent *et al.*, 2009a).

Resilience

Higher intelligence, a warm and supportive relationship with parents, more adaptive emotion regulation skills, and a problem-focused coping style can protect at-risk youth from developing depression (Yap *et al.*, 2008; Brent *et al.*, 2009a; Wetter & Hankin, 2009).

Neurobiology of depression

Hypothalamic pituitary adrenal axis

A meta-analytic review found that pediatric depression was associated with dexamethasone suppression test nonsuppression, higher levels of basal cortisol, and an increased cortisol response to social stressors (Lopez-Duran *et al.*, 2009). High nocturnal urinary cortisol predicts depressive recurrences, especially in youth exposed to life stressors (Rao *et al.*, 2009).

Inflammation

Inflammation may play a role in the pathophysiology of depression, through neurotoxicity and interference with serotonin metabolism (Mills *et al.*, 2013), with increased levels of interleukin factor 6 (IL-6) and C-reactive protein (CRP) in depressed youth (Mills *et al.*, 2013). Prospective studies link early adversity, inflammatory markers, and depressive symptoms (Danese *et al.*, 2008, 2009; Miller & Cole, 2012), although some studies show that inflammation is a consequence rather than a precursor of depression (Copeland *et al.*, 2012). Some posit that inflammatory processes found in depression may account for the high rate of cardiometabolic illness in depression (Mills *et al.*, 2013).

Neurocircuitry of depression

The current neural model of depression is consistent with studies implicating cognitive bias and emotion regulation in the pathogenesis of depression. Neuroimaging studies in pediatric depression find alterations in circuits related to biased information processing, for example, with greater attendance to negative emotional cues, less ability to use prefrontal cortical resources to dampen limbic activation to negative emotional cues, and impaired ability to experience positive affect and reward (Hulvershorn *et al.*, 2011). These characteristics are present both in youth at risk for depression as well as depressed youth.

Structural studies

Cortical thinning of the lateral half of the right hemisphere and medial aspect of the left, as well as bilateral hypoplasia of frontal and parietal white matter, have been reported as a familialy transmitted phenotype for depression (Peterson & Weissman, 2011). Small hippocampal volume has been identified as a risk factor for depression, especially in interaction with early-life adversity (Rao *et al.*, 2010). Contradictory findings about amygdala size and depression may be explained by the impact of antidepressant medication on subcortical structures (Hamilton *et al.*, 2008; Hulvershorn *et al.*, 2011).

Biased information processing

Peripheral neurocognitive studies

A bias toward sad (vs happy) words on the affective go/no go task was found in acutely depressed but not remitted depressed youth (Maalouf *et al.*, 2012a). Depressed youth respond faster to sad faces as compared to healthy controls and are more easily distracted by negative emotional stimuli while performing cognitive tasks (Ladouceur *et al.*, 2005, 2006).

fMRI studies

Depressed youth, compared to controls, show greater reactivity to negative emotional stimuli in the amygdala, dorsal anterior cingulate cortex (ACC), and insula, and show less reactivity in the dorsolateral prefrontal cortex (DLPFC) to negative stimuli and when performing higher order cognitive tasks (Roberson-Nay *et al.*, 2006; Monk *et al.*, 2008; Halari *et al.*, 2009; Hulvershorn *et al.*, 2011).

Studies of resting state connectivity are consistent with the above-noted findings, supporting the view that the diathesis for depression involves diminished prefrontal cortical modulation of limbic activity. Depressed youth and youth at risk for depression, compared to controls, have diminished connectivity between the amygdala and DLPFC (Luking *et al.*, 2011). Depressed adolescents, and even depressed preschoolers, show evidence of difficulty in emotion processing, with decreased functional connectivity in a subgenual ACC-based neural network (Cullen *et al.*, 2009; Gaffrey *et al.*, 2010). Two studies using diffusion tensor imaging (DTI) in depression have found decreased fractional anisotropy (FA) in the uncinate fasciculus, a white matter tract connecting the ventral prefrontal regions (including the subgenual ACC and ventromedial PFC) with the amygdala (Cullen *et al.*, 2010; Huang *et al.*, 2011).

Positive affect and reward processing

Attenuated positive affect, rather than just excess negative affect, may also be a risk factor for early onset depression (Olino *et al.*, 2011). The interaction of high negative emotionality and low positive emotion predicted growth in anhedonic symptoms, although this relationship was buffered by the experience of supportive relationships (Wetter & Hankin, 2009). Low positive affect, even in positive contexts, is also found in youth at increased familial risk for depression (McMakin *et al.*, 2011).

fMRI studies demonstrate that, in response to a reward decision-making task, depressed adolescents exhibit a blunted response in the striatum, ACC, caudate, and orbito-frontal cortex during reward anticipation and reward outcome, compared to controls (Forbes & Dahl, 2012), suggesting a decreased emotional response to a reward. In addition, in a similar reward task, high-risk subjects show less activation in the right insula compared to a low-risk control group (Gotlib *et al.*, 2010).

Treatment

Overview

Treatment of depression is divided into three stages: (i) acute treatment (first 2–3 months); (ii) consolidation (subsequent 3–6 months), and (iii) continuation (continuing treatment for 12+ months). The goal of acute treatment is to achieve a response, usually defined as at least a 50% decline in depressive symptoms and a global rating of improved or very much improved. Consolidation involves either continuation of the same treatment, or adjusting the treatment to address residual symptoms in order to achieve remission. The type and intensity of treatment depends on severity, and so we provide definitions of mild, moderate, and severe depression in Table 63.1. The magnitude of the effect for treatments are reports with an effect size (*d*), or number needed to treat (NNT), which is the inverse of the difference in response between drug and placebo, so that the smaller the NNT, the greater the treatment effect. The number needed to harm (NNH) is an analogous metric for

Table 63.1 Levels of severity of depression.

Level of severity	Number and type symptoms	Impairment
Mild	≤4, no suicidal ideation or psychosis	Able to function in most ways, but takes more effort
Moderate	5–6, suicidal ideation	Impairment in at least one domain
Severe	7, imminent suicidal risk, could have psychosis, mixed features	Unable to function adequately, with impaired self-care

adverse events. Table 63.2 summarizes findings from recent, large clinical trials.

Acute treatment

Many patients with mild depression respond to assessment and education alone (Birmaher *et al.*, 2007). For moderate-to-severe depression, evidence-based treatments are cognitive behavior therapy (CBT), antidepressant medication, and interpersonal psychotherapy (IPT), or combinations of medication and psychotherapy. For more detailed discussions of psychosocial treatments and CBT specifically, see Chapters 36 and 38.

CBT

CBT focuses on identifying cognitive distortions that may lead to depressed mood and also utilizes problem solving, behavior activation (BA), and emotion regulation skills to help manage and combat depression, with an average of 8–16 sessions. BA helps the patient to identify and participate in activities that are likely to lead to pleasure or mastery and can help relieve depressive symptoms (Lewinsohn *et al.*, 1998). A meta-analysis shows that CBT shows a small to moderate effect on depression, relative to alternative treatments (*d* = 0.35) (Weisz *et al.*, 2006). CBT performs better than supportive, family, and relaxation therapies in acute trials, although these alternative treatments catch up during longer-term follow-up (Wood *et al.*, 1996; Brent *et al.*, 1997; Birmaher *et al.*, 2000). In a community-based effectiveness trial comparing CBT to treatment as usual, CBT produced similar outcomes as treatment as usual, but with fewer sessions, less use of other services, and greater parental satisfaction (Weisz *et al.*, 2009). In the Treatment of Adolescent Depression Study (TADS), a multicenter study that randomized 439 depressed adolescents to CBT alone, fluoxetine alone, CBT with fluoxetine, or pill-placebo, by 12 weeks, CBT alone did not perform better than placebo, and was inferior to medication alone or medication in combination with CBT (March *et al.*, 2004). However, by 18 weeks, the CBT alone group had similar outcomes to the other active treatments (March *et al.*, 2007). Naturalistic data suggest that an adequate response may require at least nine sessions (Kennard *et al.*, 2014). Mediational analyses support that CBT works via the relief of cognitive distortions,

Table 63.2 Summary of some of the more recent clinical trials in adolescent depression.

Study	Sample	Outcome	Primary findings (% outcome)					Predictors/moderators of poorer response
Treatment of Adolescent Depression Study (TADS)	439 youth 12–18 yrs. with MDD Mean CDRS-R = 60 Suicidal = 29% Comorbid = 60%. Randomized to FL, CBT+FL, CBT, PL	CGI-I ≤ 2	Wks 12 18 36	FL 61 69 81	CBT + FL 71 85 86	CBT 43 65 81	PL 35 — —	<p>Predictors: severity, chronicity, hopelessness, suicidal ideation</p> <p>Moderator (of CBT): lower income, sexual abuse, family discord, severity, low cognitive distortion</p> <p>Predictors of suicidal events: Highest in FL, predicted by baseline ideation, slower response</p> <p>Fastest response in CBT+FL, and highest rate of early remission at 12 weeks (37% vs. 17–23%)</p>
Adolescent Depression Antidepressant and Psychotherapy Trial (ADAPT)	208 youth 11–17 yrs., ≥ 4 DSM-IV depressive symptoms Mean CDRS-R = 59 Suicidal = 66.3% Comorbid = 89% Randomized to FL, CBT+ FL	CGI-I ≤ 2	Wks 12 28	FL 44 61	CBT + FL 42 53			<p>Predictors of nonresponse: OCD symptoms, suicidal ideation, severity</p> <p>Predictors of suicidal events: Family dysfunction, high ideation, NSSI</p>
Treatment of SSRI-Resistant Depression in Adolescents	334 youth 12–18 yrs., MDD and did not response to adequate trial with an SSRI Mean CDRS-R=59 Suicidal = 58% Comorbid = 52% Randomized to new SSRI, new SSRI+CBT, VLX, VLX+CBT	CGI-I ≤ 2 and CDRS-R % change from baseline $\geq 50\%$	Wks 12 24 48 72	SSRI 39 58 56 62	CBT + SSRI 55 54 54 54	VLX 42 53 58 59	VLX + CBT 54 58 54 54	<p>Correlates: Drug and Alcohol use, manic symptoms, adherence, drug levels</p> <p>Predictors: Severity, family conflict, NSSI</p> <p>Moderators (of combined): (negative): abuse history; (positive): comorbidity</p> <p>Predictors of suicidal events: drug and alcohol use, slow response, high ideation, family conflict, NSSI</p>
Primary Care-Based Effectiveness Trial	152 youth with depression, 11–17 yrs, CDRS-R=35	Absence of depression diagnosis	Wks 12 26 52	SSRI + UC 72 82 94	CBT + SSRI 77 89 89			<p>Significant difference favoring combined treatment on SF-12</p> <p>Lower dose of SSRI in combined group</p>

Abbreviations: A-LIFE, Adolescent Longitudinal Interval Follow-Up Evaluation; CBT, Cognitive Behavior Therapy; CDRS-R, Children's Depression Rating Scale-Revised; CGI-I-Clinical Global Impressions-Improvement Subscale; FL, fluoxetine; MDD, major depressive disorder; NSSI, nonsuicidal self-injury; OCD, obsessive compulsive disorder; PL, placebo; SF-12, mental component, quality of life; SSRI, selective serotonin reuptake inhibitor; UC, usual care; VLX, venlafaxine; wks, weeks.

although one naturalistic study suggests that problem-solving and social skills training are also “active ingredients” (Kaufman *et al.*, 2005; Kennard *et al.*, 2014). In patients with higher rates of comorbidity and high levels of cognitive distortion, CBT, either alone, or in combination with medication, outperforms

other psychotherapies or medication monotherapy. However, for patients with a history of abuse or current parental depression, CBT is no better, and sometimes worse, than alternative treatments (Brent *et al.*, 1998; Curry *et al.*, 2006; Asarnow *et al.*, 2009).

With regard to Internet-based CBT interventions, one brief intervention with a 4 to 5 session problem-solving therapy for adolescents with depressive symptoms did not show a difference compared to a waitlist control condition, but a larger trial using a more extensive intervention ("Master Your Mood") in youth aged 16–25 showed a substantial difference in outcome, favoring the intervention over a waitlist control condition (NNT = 3; $d = 0.94$) (Hoek *et al.*, 2012; van der Zanden *et al.*, 2012). One RCT with a computerized CBT tested the effects of the intervention versus a waitlist control in youth excluded from mainstream education and with significant depressive symptomatology, and found highly significant effects on remission as rated by clinical interview (NNT = 3) and self-reported depression (Fleming *et al.*, 2012).

IPT

IPT conceptualizes depression as being related to loss, role conflict, and interpersonal discord. Accordingly, IPT aims to help depressed individuals decrease interpersonal conflicts by teaching interpersonal problem-solving skills and helping to modify dysfunctional communication and relational patterns (see Chapter 40). In the modification of IPT for adolescents (IPT-A), parent–child dyadic sessions focus on relief of parent–child conflict, an important contributor to the onset and persistence of early-onset depression. In clinical trials, IPT was delivered in 10–16 sessions, and performed better than supportive clinical management and usual care (Klomek & Mufson, 2006). IPT has not been tested against pill-placebo or medication only, but, in the two trials comparing CBT and IPT for depressed adolescents by the same research group, one trial favored IPT and the other, CBT (Rossello & Bernal, 1999; Rossello *et al.*, 2008). IPT is especially effective compared to clinical management or usual care for depressed adolescents who have poorer interpersonal functioning, high levels of interpersonal conflict with parents, higher depressive severity, and comorbid anxiety (Gunlicks & Weissman, 2008; Young *et al.*, 2009; Gunlicks-Stoessel *et al.*, 2010).

Other psychotherapies with at least one RCT

Family-based attachment therapy (FBAT), which focuses on fostering a positive and supportive relationship between parents and teens, has been shown in two studies to be superior to either a waitlist control or a brief clinical management intervention; a larger trial for suicidal adolescents is now being conducted with a stronger comparator treatment to learn if the effects of ABFT are specific to the treatment or are due to a greater number of sessions in ABFT (Diamond *et al.*, 2002, 2010).

Mentalization-based treatment (MBT) is a year-long individual psychodynamically derived intervention, with monthly family sessions that enhance the capacity of patients and their parents to understand actions in terms of thoughts and feelings, and thus improve agency and self control. MBT, compared to usual care, resulted in significantly greater improvements in self-harm and depressive symptoms, in self-harming adolescents

with borderline personality disorder and depressive symptomatology (Rossouw & Fonagy, 2012).

Medication monotherapy

Fluoxetine is the only agent recommended for use in adolescents by the National Institute for Health and Care Excellence (NICE) guidelines, and approved by the US Food and Drug Administration (FDA) for both preadolescent and adolescent depression. It shows the strongest treatment effects of any antidepressant for depressed youth (NNT = 5), although it is unclear if this is attributable to the medication or to the quality of these studies (Bridge *et al.*, 2007). Escitalopram is approved by the FDA for the treatment of adolescent depression, and is the pharmacologically active isomer in citalopram. Sertraline has also been reported to be superior to placebo, although the NNT was 10 (Bridge *et al.*, 2007). Paroxetine is now not recommended for the treatment of pediatric depression because the aggregate trial data do not support efficacy (Bridge *et al.*, 2007). Also, tricyclic antidepressants are not efficacious against child or adolescent depression (Hazell *et al.*, 2002). While there have been no head-to-head comparisons of antidepressants for the acute treatment of adolescent depression, the efficacy of citalopram was found to be similar to that of fluoxetine, and both SSRIs were similar in efficacy to venlafaxine for treatment-resistant depression (Brent *et al.*, 2008). One critique of pediatric antidepressant trials has been the high placebo response (49%) (Bridge *et al.*, 2007). Studies that recruited from fewer sites and enrolled more severely ill participants had lower placebo response rates and were more likely to find significant differences between drug and placebo (Bridge *et al.*, 2009).

Clinical severity, poor sleep, comorbidity, and family conflict predict a poorer response to SSRIs (Emslie *et al.*, 1998; Curry *et al.*, 2006; Asarnow *et al.*, 2009; Emslie *et al.*, 2012). Nonadherence and lower drug concentration have also been associated with a lower response rate to SSRIs (Sakolsky *et al.*, 2011; Woldu *et al.*, 2011). Certain symptom clusters, such as anhedonia and subsyndromal manic symptoms, may also make response to treatment (medication with or without CBT) less likely (Maalouf *et al.*, 2012b; McMakin *et al.*, 2012).

While the risk for a suicidal event (defined as an increase in suicidal ideation or an actual suicide attempt) is increased in those treated with an antidepressant compared to placebo, its incidence is rare, with an NNH of 112, meaning that 11 times as many adolescent patients benefit from an antidepressant than would experience a suicidal event (Bridge *et al.*, 2007). The risk of a suicidal adverse event is elevated 1.58-fold in drug versus placebo, with a risk difference of around 1% (Bridge *et al.*, 2007; Hetrick *et al.*, 2012). This finding is confined to those under the age of 25 (Stone *et al.*, 2009). Suicidal events tend to occur within the first 3–5 weeks and are most common in those who do not respond to antidepressant treatment, experience family conflict, have a history of nonsuicidal self-injury, and use of drugs or alcohol (Brent *et al.*, 2009b; Vitiello *et al.*, 2009; Wilkinson & Goodyer, 2011).

The concern about the association between SSRIs and suicidal events resulted in the FDA issuing a “Black Box Warning,” which has been linked to a decline in prescriptions for antidepressants and even the diagnosis of depression in American adolescents (Libby *et al.*, 2009). Pharmacoepidemiological studies, which encompass a broader and more representative sample of treated adolescents than clinical trials, show that a suicide attempt is much more common *prior* to initiation of an antidepressant than afterward, (Simon & Savarino, 2007), that greater use of antidepressants is associated with a decline in suicide rates, and that a decrease in use of antidepressants can be associated with an increase in the youth suicide rate (Gibbons *et al.*, 2005; Ludwig *et al.*, 2009). A recent meta-analysis of trials of fluoxetine examined the impact of medication on depression and suicidal events (Gibbons *et al.*, 2012). Both adolescents and adults showed a decrease in depressive symptoms relative to placebo, but only the adults also showed a decline in suicidal events, suggesting that for adolescents, antidepressant treatment alone may not be sufficient to reduce suicidal ideation, a finding consistent with the TADS study (March *et al.*, 2004, 2007).

Depressed children and adolescents show an increased risk for mania or hypomania when treated with antidepressants, with one meta-analysis finding that 9.8% of antidepressant-treated youth experienced mania or hypomania versus 0.45% of those exposed to placebo, for an NNH = 37 (Offidani *et al.*, 2013). A pharmacoepidemiological study of youth exposed to antidepressants reported a lower rate of mania or hypomania, 5.4%, and found that children and younger adolescents were more likely to have pharmacologically induced mania or hypomania than older adolescents (Martin *et al.*, 2004).

The only two non-SSRI antidepressants with some support for efficacy in adolescent depression are nefazodone and venlafaxine. Nefazodone was examined in only one study, and although the generic compound is still available, the drug is no longer marketed because of an increased risk of hepatotoxicity (Bridge *et al.*, 2007). Post-hoc analyses of two clinical trials found that venlafaxine was more efficacious than placebo for adolescent, but not preadolescent, depression, and was as efficacious as fluoxetine and citalopram for treatment-resistant depression (Emslie *et al.*, 2007; Brent *et al.*, 2008).

One small clinical trial in prepubertal and early adolescent depressed patients found that omega-3 was superior to placebo in the acute treatment of depression, but this has never been replicated (Nemets *et al.*, 2006). Although open-label studies suggest that bupropion is efficacious in treating depressed adolescents, particularly with comorbid ADHD, its efficacy has never been studied in a clinical trial (Daviss *et al.*, 2001).

Bright light

Bright light for 1 hour daily has been shown to reduce depressive symptoms in children and adolescents with seasonal affective disorder in a randomized crossover design (Swedo *et al.*, 1997). In addition, randomized trials support the use of

bright light as a monotherapy for adolescents with mild depressive symptoms, and as an add-on to medication treatment in depressed adolescents in order to accelerate antidepressant response (Niederhofer & von Klitzing, 2011, 2012).

Combination of medication and CBT

The TADS study found that the combination of CBT and fluoxetine was associated with the most rapid and complete response during acute treatment (March *et al.*, 2004; Kennard *et al.*, 2006). In the Adolescent Depression and Psychotherapy (ADAPT) study, the addition of CBT to fluoxetine did not improve outcome over fluoxetine alone (Goodyer *et al.*, 2007). The ADAPT sample may have been less likely to respond to psychotherapy because potential participants were screened out if they responded to a brief psychosocial intervention, and in contrast to TADS, participants with psychotic symptoms were allowed into the study. The addition of CBT to medication monotherapy provided in primary care was not superior to medication management alone, although measures of self-reported symptoms favored the combination (Clarke *et al.*, 2005). In a recent meta-analysis of studies of primary adolescent depression, combination treatment was found to be superior to antidepressants alone with regard to improvement of functional status (Dubicka *et al.*, 2010), but not with respect to the outcomes of response, remission, or occurrence of suicidal events. However, a Cochrane review that included clinical trials of depressed children and adolescents with depression with or without substance abuse (and therefore included studies of CBT that had a substance abuse focus) found that combination treatment was more likely to result in remission (NNT = 12), and was protective against suicidal events (NNT = 7) (Cox *et al.*, 2012a).

Continuation and maintenance

Placebo-controlled continuation trials in depressed adolescents support the continued use of an antidepressant for at least 6 months after the achievement of remission, with those patients with residual depressive symptoms more likely to relapse (Emslie *et al.*, 2008). A Cochrane review found that the likelihood of relapse was 41% in those maintained on an antidepressant versus 67% in those on placebo (OR = 0.34, NNT = 4) (Cox *et al.*, 2012b). The addition of a wellness-oriented CBT to fluoxetine during the continuation phase resulted in an even lower risk of relapse or recurrence compared to medication continuation alone (Kennard *et al.*, 2014). A quasi-experimental study also supports the utility of monthly CBT booster sessions in preventing depressive relapse (Kroll *et al.*, 1996).

Treatment-resistant depression

In the Treatment of SSRI-Resistant Depression in Adolescents (TORDIA), 334 adolescents who had not responded to an adequate trial to an SSRI antidepressant were randomized to one of four conditions using a balanced 2 × 2 design: switch to another SSRI (paroxetine, fluoxetine, or citalopram), switch to venlafaxine, switch to another SSRI plus CBT, or switch to

venlafaxine plus CBT. The 12-week response rate was similar in the two medication conditions, although the rate of side effects, and some secondary symptoms (anxiety, self-reported depression, suicidal ideation) were higher in the venlafaxine group, and the response was better for combined treatment compared to medication monotherapy (Brent *et al.*, 2008; Vitiello *et al.*, 2011). By 24 weeks, response and remission rates had converged across groups (Emslie *et al.*, 2010).

Prevention

A systematic review of school-based prevention and early intervention programs for depression (see Chapters 17 and 42) found support for CBT-based interventions, with the largest effects in those programs that had an indicated (evidence of some depressive risk) as compared to a universal frame, and with smaller effects if there was an attention control group, as compared to no intervention (Calear & Christensen, 2010). While indicated interventions have larger effects, a Cochrane review found some evidence to support the efficacy of both universal and targeted interventions to prevent the onset of depression, especially in the first 12 months of follow-up (Merry *et al.*, 2011). One large indicated prevention trial randomized 316 youth with at least one depressed parent and some evidence of subsyndromal depression to either the Coping With Depression group intervention or usual care, and showed a lower risk for depressive onset in those who received the experimental treatment at 8 (NNT = 9) and 33 months after the intervention;

current parental depression at the time of randomization was a negative moderator of intervention effect (Garber *et al.*, 2009; Beardslee *et al.*, 2013). A family group CBT intervention for offspring of depressed parents also showed a lower rate of onset of depression in the experimental treatment even 24 months after the intervention (Compas *et al.*, 2011), with the effects mediated by changes in positive parenting skills and the youths' secondary control coping (Compas *et al.*, 2010). An RCT compared a cognitive behavior (CB), interpersonal therapy-adolescent skills (IPT-AST) and a no-treatment control for high school students, and found that both CB and IPT-AST were efficacious in reducing depressive symptoms (d 's 0.37 and 0.26, respectively), especially in those with high depressive symptoms at intake (d 's 0.89 and 0.84) (Horowitz *et al.*, 2007).

Clinical approach to depressed youth

Initial assessment and management

The clinical management of depression involves several significant evaluative and therapeutic steps: determination of level of care, development of a safety plan, assessment of comorbidity and psychosocial stressors, and prioritization for treatment, and then matching available treatments to the patient and family needs and preferences (see Table 63.3). This approach is consistent with both the American Academy of Child and

Table 63.3 Initial approach to the depressed child or adolescent.

Clinical assessment/intervention	Specific guidelines
Determine level of care	<ul style="list-style-type: none"> Higher level of care if threat to self or others, failure to respond to less intensive treatment, poor functional status
Develop safety plan	<ul style="list-style-type: none"> Develop internal and interpersonal strategies for coping with suicidal urges Restrict access to lethal agents
Careful diagnostic assessment, assess comorbidity and set treatment priorities	<ul style="list-style-type: none"> Rule out bipolar disorder and seasonal affective disorder Acuity and contribution to functional status may be particularly salient for some conditions such as eating disorders, substance abuse, or parental depression that must be addressed in order to succeed with treatment of depression.
Rule out medical contributors to depression	<ul style="list-style-type: none"> For chronic or treatment resistant depression, obtain screening laboratory tests for anemia, hypothyroidism, occult inflammatory processes Review medications
Assess and address psychosocial stressors that may lead to treatment resistance	<ul style="list-style-type: none"> High levels of family conflict, parental depression, history of abuse, same sex attraction, peer victimization all may interfere with otherwise credible treatments and may need to be prioritized in order to have a successful outcome
Match patient to available treatments	<ul style="list-style-type: none"> Explain risks and benefits of psychotherapy and medication For mild depression, may provide education, support, and follow-up For moderate depression, reasonable to start with monotherapy, although combination may provide quicker and better functional outcomes For more severe depression, medication, preferably with psychotherapy, will yield the fastest and more complete recovery

Adolescent Psychiatry (AACAP) and NICE guidelines (NICE, 2005; Birmaher *et al.*, 2007).

Risk assessment and treatment planning

The first determination in the assessment of a depressed child or adolescent is whether the child can safely be treated as an outpatient. All depressed patients, but especially those with current or recent suicidal ideation or attempt, should develop a safety plan with the clinician and family to cope with suicidal urges (Birmaher *et al.*, 2007; Stanley *et al.*, 2009). Patients who say that they cannot adhere to a safety plan, or show a clinical presentation that makes it unlikely for patient adherence (e.g., mixed state, psychotic, alcohol/drug dependence) are likely to need more intensive treatment than weekly outpatient treatment, up to and including inpatient care. While hospitalization for high-risk youth is considered standard-of-care, there has not been an empirical demonstration that hospitalization, compared to a lower level of care, actually prevents suicide or suicidal behavior. Other clinical indications for a higher level of care would be lack of progress in a less intensive treatment and/or functional impairment that makes participation in daily activities (e.g. school) impossible. As a general framework, clinicians need to consider the following hierarchy of priorities: (i) life-threatening issues (e.g., suicidality, homicidality, exposure to domestic violence, intravenous drug use); (ii) therapy-threatening issues (hopelessness about treatment, chronically depressed parent who is unable to bring the child for treatment); and (iii) symptom- and functionally oriented treatment.

Patient and family education

Because depression is often a chronic and recurrent illness, the clinician should establish a long-term partnership with the patient and family. This can be achieved by providing the patient and family with all the requisite information about depression and its treatment, and then making treatment decisions collaboratively (Brent *et al.*, 2011). As described in Table 63.4, education focuses on depression as an illness, recognition and monitoring of depressive symptomatology, knowing risks and benefits of different treatments, and, if symptom relief is achieved, development of a plan to prevent relapse and recurrence.

Table 63.4 Psychoeducation: key points for parents and patients.

- 1 Depression is an illness and not the fault of the patient or family.
- 2 How to recognize and monitor depressive symptoms, and detect early relapse and recurrence.
- 3 Modal course, in order to have reasonable expectations for pace and extent of recovery.
- 4 Analyze risks and benefits of different treatment options, in order to make an informed decision.
- 5 How to collaborate in development of a plan for relapse prevention, continuation, and maintenance treatment.

Family, social, and individual context

Depressed children and adolescents who are clinically referred often have parents who have active psychiatric difficulties, most commonly depression, anxiety, or substance abuse. These difficulties may make it very difficult for the family to adhere to treatment recommendations, and may contribute to a sub-optimal clinical response in the child. Treatment of maternal depression, for example, has been shown to lead to symptomatic improvement in offspring (Gunlicks & Weissman, 2008). Abuse, exposure to family violence, or high levels of criticism or discord must be addressed because of safety issues for the child as well as the negative impact of these factors on duration and recurrence of depressive episodes. When parents are unable to provide the necessary support for treatment, they sometimes are willing to allow involvement of adult surrogates, such as older siblings, other relatives, or close friends who may temporarily step in and help with transportation and even monitoring of treatment response.

Due to decreased energy, concentration, and motivation, depressed children and adolescents often fall behind in school, which in turn leads to a sense of failure, increased anxiety, and a tendency to give up and disconnect from school. There also may be specific school-related stressors that contribute to depressive symptomatology, such as being the target of bullying or cumulative academic problems (Shamseddeen *et al.*, 2011). Therefore, the clinician should assess the depressed child's current school function, identify any school-related stressors, and, if the patient has fallen behind academically, develop a plan, in conjunction with the school, for a reduced workload and a plan for catching up that is mutually acceptable to school, family, and student.

With regard to individual context, it is important to identify and prioritize comorbid health risk behaviors or psychiatric disorders that are likely to be life-threatening or disruptive to therapy. Life-threatening behavior, like intravenous drug use, aggressive criminal behavior, or nonadherence with care for a serious chronic illness should be addressed prior to treatment of depression, even recognizing that depression may be contributing to these problems. Higher priority to targeting comorbid conditions over depression should be given if these symptoms are causing the greatest functional impairment and if the treatment of depression is not likely to be successful unless these other conditions are addressed first. For example, the treatment of a patient with both depression and ADHD, whose main difficulties are decreased motivation, suicidal ideation, and hopelessness, should probably initially focus on the depression, whereas a patient with similar comorbidity, whose depression emerges secondary to school and peer failure due to impulsivity and inattention, should probably have the ADHD addressed first.

Initial treatment approach

The first intervention for mild depression should be family education, supportive counseling, case management, and problem-solving, since there is evidence that a substantial

proportion of mildly depressed adolescents will respond to these relatively nonspecific interventions (Renaud *et al.*, 1998; Goodyer *et al.*, 2007; Bridge *et al.*, 2009).

For moderate depression, the NICE guidelines recommend use of CBT, IPT, or family therapy prior to the use of medication, whereas the AACAP guidelines recommend CBT, IPT, or medication as first-line treatments. The NICE guidelines also indicate that antidepressants should never be used without psychotherapy, whereas the AACAP guidelines indicate that while the combination treatment may be preferable, medication monotherapy is an acceptable alternative under certain conditions (NICE, 2005; Birmaher *et al.*, 2007). The rationale for the AACAP stance is that there are not enough qualified therapists to require initial treatment with CBT or IPT, some adolescents do not wish to participate in psychotherapy, and in the only head-to-head comparison of psychotherapy and medication, fluoxetine was greatly superior to CBT over the first 12 weeks (March *et al.*, 2004). With regard to the NICE recommendation requiring that pharmacotherapy always be combined with psychotherapy, while there is evidence from TADS that combination results in the fastest response and from TORDIA that combination is better than monotherapy for treatment resistant depression, one meta-analysis found that combination treatment did not improve depression and protect against suicidal events relative to medication monotherapy (Dubicka *et al.*, 2010). Therefore, we tend to favor the AACAP, more flexible approach over that recommended by NICE (and for full disclosure, the senior author helped to draft the AACAP guidelines).

For more persistent or severe depression, one of the three empirically validated treatments, SSRI medication, CBT, or IPT, or preferably, combination of medication and psychotherapy is indicated, dependent on availability and patient preference. As noted above, those with more severe depression are more likely to benefit from antidepressants, a history of abuse may interfere with CBT outcome, and those with high levels of parent-child conflict and difficulties with social functioning may do particularly well with IPT. Whatever the choice of initial treatment, the patient's progress should be reassessed in 4–6 weeks. If the patient has shown a substantial decrease in depressive symptoms and improvement in functioning, then continuing with the same treatment is reasonable, but if the patient has not responded, then a change in strategy is indicated. If the patient is currently receiving psychotherapy only, consideration should be given to adding medication; if the patient is receiving medication monotherapy, consideration is to be given to either increasing the medication dosage and/or adding psychotherapy. Also, patients should be reassessed with regard to comorbidity, presence of mania, and psychosocial stressors that may be contributing to treatment resistance. Relative contraindications for use of antidepressant medication are a history of mania or hypomania, in which case mood stabilization should be undertaken prior to the use of antidepressants, and for those with a strong family history of bipolar disorder, it may be safer to begin

with psychotherapy for the same reasons. Patients with a history of seasonal depression should be given a trial of bright light, and those with psychotic symptoms, although not carefully studied in this age group, are thought most likely to benefit from the combination of an antidepressant and an antipsychotic.

Given that the most evidence for efficacy exists for fluoxetine, this should be a first-line medication. For those who have failed to respond to fluoxetine, cannot tolerate it, or for some reason do not wish to take it, use of one of the other SSRIs for which there is some evidence of efficacy is warranted. Current clinical recommendations are to begin with half the usual initial target dose (e.g., 10 mg fluoxetine) for 1 week, to determine if the patient can tolerate the medication, and then increase to 20 mg for the next 3 weeks. If the patient is still depressed, then one can continue to increase the dosage around every 4 weeks because it takes around that amount of time to tell if an increase is going to be helpful. While the NICE guidelines state that increasing the dosage of an SSRI is not likely to be helpful, there are modest data to the contrary (Heiligenstein *et al.*, 2006; Sakolsky *et al.*, 2011). Most patients who respond to fluoxetine achieve symptomatic relief at 20–80 mg of fluoxetine. Once symptomatic relief has been achieved, treatment should continue a minimum of 6–12 months in order to prevent relapse as per both AACAP and NICE guidelines.

Sleep difficulties are common in depression and may be made worse with antidepressant treatment. Behavioral approaches to the management of sleep difficulties (see Chapter 70), and use of melatonin, shown to be efficacious in other patient populations, should be considered early in treatment, given the moderation of antidepressant response by insomnia (Emslie *et al.*, 2012).

Approach to residual symptoms

Often, even in patients who respond, there are still residual symptoms of depression, such as sleep difficulties, anhedonia, irritability, and fatigue (Vitiello *et al.*, 2011). The clinician should rule out medical causes (e.g., sleep disorder, anemia, and hypothyroidism) and possible contribution of comorbid conditions (e.g., substance abuse). Sleep difficulties can be targeted with CBT approaches, which in preliminary studies have been shown to be efficacious in youth (Clarke & Harvey, 2012). Although not studied in youth with depression, clinical trials in youth with ADHD and autism spectrum disorder support the use of melatonin to aid in difficulty falling asleep (Cummings, 2012). Expert clinical practice (although without supporting empirical evidence) supports augmentation with bupropion and/or recommendation of vigorous exercise and BA for those with residual fatigue or anhedonia (Birmaher *et al.*, 2007; Hughes *et al.*, 2007).

Treatment-resistant depression

First, it should be confirmed that the patient has already had an adequate trial of treatment, has the right diagnosis, and indeed has not shown evidence of a response. Second, one should make sure that the patient does not have untreated comorbid

conditions that would make treatment response unlikely (e.g., substance abuse, anorexia, etc.). Third, one should rule out that psychosocial stressors likely to contribute to a continuing depression (e.g., parental depression and peer victimization) are not present and have not previously been addressed.

After considering these three important points, patients who have not responded to an adequate trial with an SSRI should be switched to a second SSRI, with the addition of CBT (Brent *et al.*, 2008). Algorithms based on expert opinion recommend that if two consecutive trials with SSRI antidepressants do not result in a treatment response, a switch to another class of antidepressant (e.g., venlafaxine, bupropion) is to be considered. If patients have shown a partial response to one agent (e.g., an SSRI), algorithms recommend augmentation with an antipsychotic, bupropion or lithium, but there are no empirical studies in youth. Open treatment of adolescents with treatment-resistant depression with transcranial magnetic stimulation suggests that this intervention is feasible, safe, and possibly efficacious, supporting further study in clinical trials (Croarkin *et al.*, 2010). Electroconvulsive therapy (ECT) has not been studied systematically in child and adolescent mood disorders, but naturalistic studies suggest that the best responses are in youth with catatonia, bipolar depression, or psychotic depression (Walter & Rey, 2003). Clinical guidelines recommend that ECT be considered after a depressed patient has not responded to psychotherapy and three medication trials, with demonstrated adherence (Birmaher *et al.*, 2007).

Future clinical and research challenges

Depression in childhood and adolescence is a complex and debilitating disease that frequently has a lifelong, chronic, recurrent course. In this concluding section, we focus on the unknowns of youth depression and suggest several key areas for future investigation.

1 Identify clinically useful early biomarkers that predict treatment response and adverse events. There is some evidence in adult depression that changes in gene expression related to neurotrophic and inflammatory genes, as well as serum levels of these proteins, may predict treatment response (Mamdani *et al.*, 2011). Identification of early markers that will predict a successful course of treatment could improve fit to treatment and avoid lengthy, unsuccessful medication trials. In addition, studies of gene expression and micro-RNA levels could help identify novel therapeutic targets. fMRI, although useful for clinical research, may be impractical for clinical applications, but it would be useful to identify neurocognitive neurosignatures associated with treatment response to antidepressants and/or psychotherapy. The identification of markers to predict the development of mania or of suicidal events, in concert with markers that predict treatment response, could be useful in personalizing and optimizing treatment.

2 Identify methods to accelerate initial treatment response.

The risk for suicidal events and nonresponse is much higher in those patients who show a slow and incomplete response to initial treatment. Identification of psychotherapeutic methods (e.g., targeting sleep or anhedonia) or somatic interventions (e.g., bright light, ketamine) to accelerate treatment response in more severely depressed patients could be life saving.

3 Neurobiological effects of early adversity and developing optimal treatments.

A high proportion of clinically referred depressed youth have a history of early adversity and this history confers a risk for a poorer response to treatment (Nanni *et al.*, 2012). A better understanding of the neurobiological effects of early adversity is needed in order to translate that understanding into effective interventions for depressed youth with a history of adversity.

4 Research on the use of social media, technology (e.g., smartphones), and online material for the identification, prevention, and treatment of depression. This area of research will be increasingly important, given the growth in use of technology, increased pressure on health care providers to cut costs, and demonstration of the efficacy of Internet interventions.

CHAPTER 64

Suicidal behavior and self-harm

Keith Hawton¹, Rory C. O'Connor² and Kate E.A. Saunders¹

¹Department of Psychiatry, University of Oxford, UK

²Suicidal Behaviour Research Laboratory, Institute of Health and Wellbeing, University of Glasgow, UK

Many young people consider suicide or self-harm at some point in their lives. Some carry out nonsuicidal acts of self-harm, while fewer make suicide attempts. A small minority will die, either intentionally or unintentionally. There is a continuum of suicidality but there are also two main points at which discontinuity exists. First, of those who have suicidal ideas only a small proportion engage in some form of self-harm. This represents an important behavioral threshold. Second, some individuals engage in self-harm once, never to repeat, while others carry out multiple acts of self-harm (some repeating many times).

Definitions of terms

Suicide ideation is defined as thoughts about an act of self-harm or suicide, including wishing to kill oneself, making plans of when, where, and how to carry out the act, and having thoughts about the impact of one's self-harm or suicide on others. *Self-harm* is defined as any form of nonfatal self-poisoning or self-injury (such as cutting, taking an overdose, hanging, self-strangulation, and running into traffic), regardless of motivation or the degree of intention to die. *Suicide* includes deaths resulting directly from acts of self-harm. Official verdicts in the United Kingdom, and many other countries, are currently determined by the coroner and are classified using ICD-10 (World Health Organisation, 1996). To reach a verdict of suicide a coroner needs to be satisfied that the act was self-inflicted and that death was the intended outcome. However, strict adherence to these criteria may result in underestimation of the true extent of suicide (Gosney & Hawton, 2007).

In Section 3 (conditions requiring further study) of DSM-5, nonfatal self-harming behavior is classified into diagnostic categories of nonsuicidal self-injury (NSSI) and suicidal behavior disorder. NSSI is defined as repeated physical self-damage or self-injury that is not accompanied by suicidal intent or ideation,

and includes cutting, burning, stabbing, or excessive rubbing. NSSI is performed with the expectation that the injury produced will be minor to moderate and will not be life-threatening. "Suicidal behavior disorder" is applied to individuals with recent acts of self-harm, which they say involved any degree of suicidal intent (American Psychiatric Association, 2013). We prefer to use the term "self-harm" to cover all nonfatal acts and then to define dimensions of the behavior, including methods used, suicidal intent and other motives, and dangerousness/lethality (Kapur *et al.*, 2013a). We believe that self-cutting and other types of self-mutilation should be seen not as diagnoses but as part of the continuum of self-harming phenomena, because they can sometimes lead on to both suicide attempts and death by suicide.

Population prevalence of suicide, suicidal ideation, and self-harm

Suicide

Reported rates of suicide deaths among children and adolescents around the world vary considerably as can be seen in Table 64.1. Some of this diversity may reflect differences in definition as outlined above, and the cultural and legal mores that surround this issue. Generally, more males than females die by suicide in all countries for which data are published, with the exception of China and, possibly, India (Aaron *et al.*, 2004). In several countries, rates of suicide are higher in indigenous or aboriginal populations, particularly among young people. For example, First Nations people in the United States (US Department of Health and Human Services, 2004), Metis and Inuit in Canada (Kirmayer *et al.*, 1996), Australian Aborigines (Tatz, 2001), and New Zealand Maori (Ministry of Health, 2005) are overrepresented in suicide statistics. Historically, the rate of suicide among Black people in the United States has been considerably lower than White people (Bingham *et al.*, 1994); however, from 1980 to 1995

Table 64.1 Male and female suicide rates for children, adolescents, and young adults for selected countries (World Health Organization, 2014).

Country	Year	Male age-specific rate per 100,000 population		Female age-specific rate per 100,000 population	
		5–14 years	15–24 years	5–14 years	15–24 years
Australia	2006	0.4	12.2	0.1	3.5
Austria	2010	0.5	17.5	0.2	2.8
Belgium	2005	0.2	15.3	0.0	4.2

there was a dramatic increase in suicide deaths among Black youth (Joe & Kaplan, 2001).

Youth suicide rates in the United Kingdom and in several other Western countries declined during the late 1990s and early 2000s following a period in which rates in young males had been rising alarmingly. The recent worldwide economic recession may have reversed this pattern in many countries (Chang *et al.*, 2013). It should be noted that official statistics markedly underestimate the true rates of suicide, especially in children and adolescents, with some apparent suicide deaths being recorded as open verdicts, accidents, or misadventure (Gosney & Hawton, 2007). In the United Kingdom, the rate of suicide and undetermined deaths for adolescents aged 15–19 years in 2011 was 6.6 per 100,000 in males and 3.1 per 100,000 in females (The Office for National Statistics, 2013). Undetermined verdicts are not used for 10–14-year-olds.

Suicidal ideation and self-harm

A systematic review of the prevalence of suicidal phenomena in adolescents based on community and school-based studies in several countries demonstrated that averaging across studies nearly one in five adolescents reported having thought about suicide in the previous year. The mean lifetime prevalence of self-harm was 13%, with 6% self-harming in the previous 12 months. Rates of suicidal thoughts and actual self-harm were far higher among females than males (Evans *et al.*, 2005b).

In the United Kingdom, studies have been conducted on the prevalence of suicidal ideation and self-harm in the community (Hawton *et al.*, 2002; O'Connor *et al.*, 2009b). In a school-based study of 6020 students in England, 15% reported thoughts of self-harm (which had not been acted on) in the preceding year. This was much more common among females (22%) than males (9%). Seven percent had self-harmed in the past year. Self-harm was more frequent among females (11%) than males (3%) (Hawton *et al.*, 2002). There were similar findings in a study employing the same methodology in Scotland (O'Connor *et al.*, 2009b). In contrast, in a large national study of suicidal phenomena among children and adolescents of 5–15 years, based on parental report, only 1% of 5- to 10-year-olds had ever tried to harm, hurt, or kill themselves, rising to 2% among those aged 11–15 years (Meltzer *et al.*, 2001). Parents are often unaware of self-harm acts by their offspring (Meltzer *et al.*, 2001; Huey *et al.*, 2004; Sourander *et al.*, 2006b), especially where self-cutting is involved.

In an international comparative study, again using the same methodology as Hawton *et al.* (2002), rates of self-harm in adolescents in the United Kingdom, Australia, Belgium, Ireland, and Norway were similar, but were considerably lower in the Netherlands and Hungary (Madge *et al.*, 2008).

There appear to be some differences between rates of self-harm in children and adolescents of different ethnic groups. Hispanic youth, particularly females, in the United States (Canino & Roberts, 2001) and Maori youth in New Zealand

(Adolescent Health Research Group, 2005) show higher rates than their contemporaries. In the United Kingdom, self-harm appears to be less common among Asian (7%) and Black (7%) girls than White girls (12%) but similar among Asian and White males (3%); (Hawton *et al.*, 2002). More recent studies have reported similar or lower rates of self-harm among Asian youth (Bhugra & Bhui, 2007).

Methods of suicide and self-harm by gender and international differences

There is significant variation between cultures in the methods most commonly used for suicide. The preferred methods of suicide in any given country may have an impact on suicide rates, given that some methods are potentially more lethal than others. In addition, deaths involving a certain method may increase or decrease depending on the availability of that method (Hawton, 2005). Firearms are the most common method of suicide in young people in the United States, but account for a relatively small number of deaths in the United Kingdom, New Zealand, and Australia, where availability is strictly regulated. Substitution of methods relies on both the acceptability and availability of alternative methods. Increasing rates of hanging in young people suggest that it has become a more acceptable method of suicide (Centre for Disease Control and Prevention, 2010).

Charcoal burning has spread from Hong Kong to Taiwan and Japan: the apparent increased acceptability, cultural meaning, and preference for methods of suicide such as this require further research, including the likely role of the media, especially the Internet (Biddle *et al.*, 2013).

In India, in contrast with other countries, hanging is a more frequent method of suicide in girls (57%) than boys (50%), whereas poisoning is slightly more common in boys (50%) than girls (37%) (Lalwani *et al.*, 2004). The use of toxic pesticides in agrarian communities such as in China, India (Prasad *et al.*, 2006), and Sri Lanka (Eddleston *et al.*, 2005a) means that a similar method (self-poisoning) is associated with much higher mortality in these countries than in countries where analgesics and other medications are the most frequently used substances for self-poisoning. The medical management of pesticide poisoning is difficult and a lack of adequate medical services and distances to hospitals in developing countries may elevate death rates (Eddleston *et al.*, 2005b).

At the community level, the most common methods of self-harm in the United Kingdom and many other countries are cutting and overdose (Hawton *et al.*, 2002). However, only a minority of young people engaging in self-harm in the community go to hospital. In studies based on presentations to general hospitals in the United Kingdom, the majority of adolescents had harmed themselves by taking an overdose, self-poisoning with analgesics being particularly common (Hawton *et al.*, 2012b).

Puberty and self-harm

Self-harm increases rapidly during the early teenage years. The female to male gender ratio is particularly high at

this time, especially around age 13–15 years. In a survey of 12–15-year-olds in schools in Australia and the United States, the onset of self-harm was found to be related to pubertal phase, especially late or completed puberty, rather than chronological age. This was particularly marked in girls and for self-cutting (Patton *et al.*, 2007). The association of self-harm with puberty and affective symptoms may be related to emerging evidence of a period of particular neurodevelopmental vulnerability around this time, with increased risk of emotional disorders (Blakemore, 2008), risk-taking behaviors, and susceptibility to negative social cues, including ostracism and the expectations of others.

Motives for self-harm

Both adolescents who present to hospital following self-harm (Hawton *et al.*, 1982) and those who are identified through community surveys to have self-harmed (Rodham *et al.*, 2004) choose a wide variety of motives (or reasons) to explain their acts. These include both motives about dealing with intolerable distress (e.g., to die, to escape) and motives related to influencing the behavior or attitudes of other people (e.g., to get someone to change their mind). They also very often choose multiple motives. Differences have been found between adolescents who cut themselves and those who take overdoses, with those who cut themselves more often saying that the behavior was related to tension reduction or self-punishment (Rodham *et al.*, 2004).

Risk factors associated with suicidal phenomena in young people

An overall model of suicidal behavior can help the clinician or researcher conceptualize the main contributory factors identified in a wide range of research studies (Figure 64.1). This can also provide a framework to support formulations and treatment planning. In such a model (Hawton *et al.*, 2012c), suicidal behaviors are viewed as the endpoint of a complex interplay between genetic, biological, psychological, psychiatric, and social risk factors which combine to increase the likelihood of self-harm or suicide (Figure 64. 1). The risk factors associated with fatal and nonfatal suicide behaviors among adolescents have been reviewed recently by Hawton *et al.* (2012c) and Hamza *et al.* (2012).

Family history and genetic influences on suicidal behavior

Research consistently indicates that a family history of suicidal behavior is associated with increased risk for suicide deaths (Brent *et al.*, 1994; Gould *et al.*, 1996; Agerbo *et al.*, 2002) and for nonfatal self-harm and suicidal ideation by adolescents (Roy *et al.*, 1997; Hawton *et al.*, 2002; Mittendorfer-Rutz *et al.*, 2008). Having a suicidal family member may suggest to adolescents that suicide is a possible solution to overwhelming psychological pain (Roy *et al.*, 1997), although the detrimental effects of living

with a parent who has undiagnosed or undertreated mental health problems are also significant (see Chapter 28). More work is required to clarify the extent to which suicidal behavior can be considered as a construct that is transmitted through families independently of the established association with familial risk of depression, impulsivity, and other psychopathology (Brent & Mann, 2005). The risk in these families is not entirely accounted for by the increased rates of psychiatric disorder. Twin studies have shown that the concordance for fatal and nonfatal suicidal behavior is higher among monozygotic than dizygotic twins (Roy, 1993; Tidemalm *et al.*, 2011). Impulsive aggression also shows heritable influences and contributes to suicidal behavior (for a review see Brent & Mann, 2005). The clustering of suicidal behavior in families cannot be explained entirely by behavioral imitation (Brent & Mann, 2005). Importantly, adoption studies have shown elevated rates of suicide among the biological relatives of adoptees who die by suicide compared with those of nonsuicidal adoptees (Roy *et al.*, 1997), including biological siblings of adoptees compared with their adopted siblings (Petersen *et al.*, 2013). Adoption studies also show the importance of environmental influences (Wilcox *et al.*, 2012).

Deviations in the serotonin system are one of the most robust neurobiological findings associated with suicidal behavior (Asberg & Forslund, 2000). The relationship between serotonin dysregulation and suicidal behavior may reflect poor impulse control, which is observed in suicidal, violent, and impulsive behaviors. Dysregulation of serotonin function may predispose a person experiencing stressful events to react impulsively (Mann *et al.*, 2001).

The main focus of interest in the genetic studies of suicidal behavior has been on three gene types: tryptophan hydroxylase (TPH), serotonin transporter (SERT), located on chromosome 17, and serotonin A receptor genes. Serotonin transporter polymorphisms, particularly the “short” allele of the promoter variant 5HTTLPR, have been associated with suicidal behavior in adults with psychiatric disorder and in particular violent attempts (Lin & Tsai, 2004) but results are

inconsistent. More recent studies in adults have explored a model of anxiety and stress responses underpinning suicidal behavior, with particular focus on cannabinoid receptors (CB1), corticotropin-releasing hormone (CRH), glucocorticoid receptors, and gamma-aminobutyric acid (GABA) (Bondy *et al.*, 2006). Despite the interest in this area, to date there are relatively few replicated findings or meta-analyses, particularly in children and adolescents.

Psychological characteristics

Psychological characteristics associated with suicidal ideation and behavior include hopelessness (Evans *et al.*, 2004; Taliaferro *et al.*, 2012), dichotomous (all or nothing) thinking, negative biases in future judgment (Pfeffer, 2000; Williams & Pollock, 2000; O'Connor, 2011), and an external locus of control (Kienhorst *et al.*, 1992). Impaired social problem solving is another contributory factor (Speckens & Hawton, 2005; Arie *et al.*, 2008; Labelle *et al.*, 2013). Impaired decision making is also associated with suicide attempts in adolescents (Bridge *et al.*, 2012).

New theoretical models also offer considerable promise in terms of better understanding the psychological processes that underpin suicidal behavior (Joiner, 2005; Van Orden *et al.*, 2010; O'Connor, 2011; O'Connor *et al.*, 2013). Extending the stress-diathesis explanations, the interpersonal model of suicide (Joiner, 2005) and the integrated motivational-volitional model (O'Connor, 2011) suggest that the extent to which individuals feel defeated or trapped, and the degree to which they consider themselves to be a burden on others and that they do not belong, are associated with suicidal behaviors. These models also highlight the importance of distinguishing the factors which are associated with whether an individual actually engages in suicidal behavior (enactor) from those which relate to suicidal thinking only (ideation only). For example, adolescents who self-harm are more impulsive and are more likely to know others who have self-harmed compared to those who have had thoughts of self-harm but have never engaged in self-harm (O'Connor *et al.*, 2012).

Certain personality characteristics such as impulsivity, aggression, neuroticism, perfectionism, irritability, and trait anxiety may act as intermediate factors that are relatively independent from major psychiatric disorders (Bridge *et al.*, 2006). Perfectionism may be particularly risky among those young people who believe that others have excessively high expectations of them (Hewitt *et al.*, 1997; O'Connor, 2007; O'Connor *et al.*, 2009b; Roxborough *et al.*, 2012). Trait optimism protects against self-harm (O'Connor *et al.*, 2009a). Social connectedness, peer attachment, and effective problem-solving skills may also offer protection (Speckens & Hawton, 2005; Hall-Lande *et al.*, 2007).

Poor physical health related to psychological problems

Poor physical health and many chronic illnesses are associated with increased risk for suicidal ideation (Suris *et al.*, 1996) and self-harm (Evans *et al.*, 2004). Furthermore, depressed adolescents commonly present with psychosomatic complaints such as headaches, loss of energy, chest pain, abdominal pain, or other physical symptoms.

Family factors

Longitudinal community studies have shown that difficulties in parent-child relationships, including those related to early attachment problems, perceived low levels of parental caring and communication are related to increased risk of suicide and suicide attempts among children and adolescents (Fergusson & Lynskey, 1995; Fergusson *et al.*, 2000; Ackard *et al.*, 2006); similar observations have been made in clinical samples (Lessard & Moretti, 1998; Pfeffer, 2000). Several reviews have concluded that adolescents from families that have experienced parental separation or divorce are at increased risk of suicide behavior, particularly among females (e.g., (Brent *et al.*, 1994; Gould *et al.*, 1996; Beautrais, 2001). Unsurprisingly, it seems that conflict between parents, both before and after their relationship ends, has a detrimental impact on children.

Childhood sexual and physical abuse are strongly associated with suicide attempts and NSSI in community and clinical samples of adolescents (Beautrais, 2001; Evans *et al.*, 2005a; Taliaferro *et al.*, 2012; Isohookana *et al.*, 2013). In addition, childhood sexual abuse is associated with adult suicide attempts (Perez-Fuentes *et al.*, 2013). Parental history of childhood sexual abuse is also associated with an increased risk of suicide attempts among offspring (Brent *et al.*, 2002).

Peers, including the influence of peer suicidal behaviors and suicide clusters

Peers can have extremely important roles in both self-harm and suicide. As noted below, relationship problems may be a common precipitant, especially in older adolescents. Self-harm can have a "contagious" quality in adolescents and exposure to self-harm by peers appears to be a key risk factor for self-harm (Hawton *et al.*, 2010; Madge *et al.*, 2011). This particularly

applies to females and to self-cutting. Suicides can occur in clusters (i.e., related in time and place) in young people (Haw *et al.*, 2013). It has been estimated that 1% of suicides in young people occur in clusters. However, with the massive proliferation of electronic communication the potential for clusters of suicides (not necessarily geographically close) may have increased.

Sexual orientation

Gay, lesbian, and bisexual young people are at increased risk of engaging in self-harm and suicide attempts (King *et al.*, 2008; Haas *et al.*, 2011), with estimates of risk ranging between two and six times that of heterosexual young people (Gould *et al.*, 2003). It is not yet clear whether increased rates of death by suicide are related to sexual orientation (Gould *et al.*, 2003). However, gay, lesbian, and bisexual youth are more likely to experience risk factors associated with suicide, particularly mental health difficulties (King *et al.*, 2008).

Environmental factors

School dropout

Several reviews of studies of young suicide attempters (Beautrais *et al.*, 1996; Evans *et al.*, 2004) and those who die by suicide (Gould *et al.*, 1996) have indicated that more have had school-based difficulties and/or have dropped out of school than have nonsuicidal adolescents. Dropping out of school has been shown to be a risk factor for suicide attempts in Western and non-Western countries (Daniel *et al.*, 2006; Donald *et al.*, 2006; Tang *et al.*, 2009). Children and adolescents who remain in school but have special educational needs appear to have higher rates of suicidal phenomena than their peers without such needs (Meltzer *et al.*, 2001; Denny *et al.*, 2003).

Proximal risk factors/life stressors

Psychological autopsy studies suggest that, compared with controls, young people who die by suicide experience higher rates of exposure to recent stressful life events such as rejection, conflict, or loss following the breakup of a relationship (Marttunen *et al.*, 1993; Brent *et al.*, 1996; Beautrais, 2001; Donald *et al.*, 2006), and disciplinary or legal crises (Marttunen *et al.*, 1998). Bullying, in particular, is associated with poor mental health, suicide ideation, and all types of self-harm (see Chapter 26). There has been recent concern about suicides by young people allegedly bullied by peers via text messaging and social networking sites, so-called "cyberbullying" (Brunstein Klomek *et al.*, 2010; Hawton *et al.*, 2012c). This issue requires urgent research attention.

Another proximal stressor is becoming intoxicated: a short-term solution that many adolescents engage in following crises—but which leads to impaired judgment and decreased inhibition, and hence to suicidal behavior (Apter & Freudenstein, 2000).

Asylum seeking and cultural factors

Refugees and asylum seekers face particular psychosocial stressors that are likely to have an impact on young people and their families. Unemployment, social isolation, and the difficulties

involved in applying for asylum experienced by parents are factors that, together with the high rates of depression, anxiety, and posttraumatic stress disorder (PTSD) in this population, may lead to suicidal behavior (Sultan and O'Sullivan, 2001; Keller *et al.*, 2003; Fazel *et al.*, 2005). Indeed, research in the Netherlands showed higher rates of suicide and suicide attempts among asylum seekers compared to the reference population (Goosen *et al.*, 2011). Racial discrimination is another factor which ought to be considered when evaluating risk of suicidal behavior. Research from the United States suggests that perceived discrimination is associated with suicide attempts in young adults (mean age 18.8 years) from different ethnic backgrounds (Gomez *et al.*, 2011). It is also important to consider cultural background when assessing risk of suicide and self-harm (Langhinrichsen-Rohling *et al.*, 2009). For example, among adolescents from East-Asian backgrounds, the shame of failing to meet familial expectations may be a precursor to suicidal behavior (Zane & Mak, 2003; Goldston *et al.*, 2008). Cultural influences may also adversely affect help-seeking. For example, help-seeking for mental health problems may be culturally stigmatized, so even in cultures where the gravity of the problem is acknowledged, cultural influences may constrain the young person from seeking help (Freedenthal & Stiffman, 2007).

Psychiatric disorders associated with self-harm and suicide

Many studies have demonstrated high rates of mental illness in adolescents engaging in both fatal and nonfatal suicidal behavior and rates are of similar magnitude to that seen in adult populations (for reviews see Evans *et al.*, 2004; Hawton *et al.*, 2013b; Figure 64.2). Although mental illness is present in many children and adolescents who engage in suicidal behaviors, clearly not all people who experience mental illness engage in suicidal behavior, so it may be a strong precursor but not a complete explanation.

In a systematic review of psychological autopsy studies (Cavanagh *et al.*, 2003) results of seven studies of adolescents or young adults suggested that 47–74% of suicides examined were attributable to a mental disorder, of which affective disorders made the greatest contribution. This review also highlighted that comorbidity, particularly comorbidity of mental disorder and substance abuse, made a strong contribution to the risk of suicide. An earlier review (Marttunen *et al.*, 1994) indicated that antisocial behavior was present in 43–73% of suicide deaths in adolescents, often in combination with depressive symptoms and/or substance abuse. Several more recent psychological autopsy studies (Houston *et al.*, 2001; Portzky *et al.*, 2005; Fortune *et al.*, 2007) suggest an interaction between mental illness, substance abuse, and interpersonal problems (and, for some, antisocial behaviors). In a case-control study of young people who had died by suicide, serious suicide attempters and a non-suicidal control group, the same risk factors of mood disorder,

Figure 64.2 Prevalence of mental disorders in children and adolescents attending general hospitals following self-harm.

requirement for psychiatric care, educational disadvantage, and stressful life events were associated with both death by suicide and serious attempts (Beautrais, 2003).

Depression is the most common mental health disorder reported in psychological autopsy studies of young people dying by suicide (see Chapter 63). The course of depression across adolescence also appears to influence suicidality. In a longitudinal study of 193 children and adolescents, persistent depression was associated with significantly higher rates of suicidal ideation and suicide attempts. Depressed females were more likely to experience recurrent episodes, while males tended to experience more persistent mood disorder (Dunn & Goodyer, 2006).

Bipolar disorder (see Chapter 62) is associated with elevated rates of suicide attempts, with the lifetime prevalence ranging from 20% (Strober *et al.*, 1995) to 44% (Lewinsohn *et al.*, 2003). In the only prospective study exploring risk of suicide attempts among youth with bipolar disorder, persistent depressive symptoms, active substance misuse, mixed affective states, and a family history of depression were all found to predict significant risk of suicidal behavior (Goldstein *et al.*, 2012).

Anxiety (see Chapter 60) and subdiagnostic anxiety symptoms were found to be associated with an increase in suicidality in a study of 12,395 adolescents from 11 different countries (Balazs *et al.*, 2013).

Substance abuse disorders, including cigarette smoking, are associated with increased risk of self-harm (Evans *et al.*, 2004; Moran *et al.*, 2012) and suicide (see Chapter 66). Clinically, it can be difficult to establish if substance abuse precedes or follows the mental health difficulties and suicidal phenomena. Adolescence is a period when both suicidal behavior and substance misuse increase and poor impulse control is a risk factor for both (Hawton *et al.*, 2012c).

Psychotic disorders make a relatively small contribution to the overall youth suicide rate. Self-harm, however, is common in the pretreatment phase of first-episode psychosis (Challis *et al.*, 2013) and was present in nearly three-quarters of those presenting to services for the first time (Harvey *et al.*, 2008), the majority describing the act as a means of responding to the distress of

their symptoms rather than as a direct result of command or passivity experiences. Depression, early age of onset, substance misuse, and duration of untreated symptoms are risk factors for self-harm in first-episode psychosis (Challis *et al.*, 2013).

Antisocial behavior is a risk factor for self-harm among females although, perhaps surprisingly, the relationship is less clear for males (Evans *et al.*, 2004). Many of the risk factors for conduct disorder are also risk factors for self-harm, including family disruption, childhood abuse, personal and familial substance abuse, and negative life events (Apter & Freudenstein, 2000).

Eating disorders and poor body image are associated with suicidal phenomena (Brausch & Gutierrez, 2009) and some consider starvation to be a form of suicidal behavior that obviates the need for other methods. Suicide risk in anorexia nervosa has been estimated to be 2–15% and 0.4–2% for bulimia nervosa, with higher rates among adolescent males than females with eating disorders (Dancyger & Fornari, 2005).

Attention deficit/hyperactivity disorder has a modestly elevated risk for fatal and nonfatal suicidal behavior, particularly in males, mediated by comorbid conditions, notably depression, conduct disorder, and substance abuse, with the risk considerably raised in young people with all three conditions (James *et al.*, 2004). A recent review of 25 studies on ADHD and suicidality also concluded that there was a positive relationship between the two phenomena (Impey & Heun, 2012).

Personality disorders in adolescence are described in Chapter 67; they are associated with suicidal ideation and attempted suicide as well as self-injury in adolescents.

Exposure to suicide and self-harm in the media, the Internet, and music

It is now well recognized that certain types of media reports and portrayals of suicide and self-harm can increase the risk of suicidal behavior (for review see Pirkis & Norderntoft, 2011). The greatest influence is probably on methods used for suicide and self-harm and seems to be particularly marked in young people. Such effects are more likely where media reporting or portrayal is dramatic, features details of a specific method of suicide, is on television, and is repeated (Stack, 2003; Pirkis & Norderntoft, 2011).

Many children appear to learn about suicide from television (Mishara, 1999), but with the proliferation of new media the relative influences of different modalities need detailed exploration. Some people may respond quickly to media presentations of suicide, acting impulsively or putting previous thoughts about suicide into action, while others may make a more considered response (Schmidtke & Hafner, 1988). Thus, in addition to potential immediate changes in suicidal behavior, media influences may also have longer term effects, by changing attitudes, providing information about methods of suicidal behavior, or planting the idea that suicide is an appropriate response to problems. It may also influence suicidal behavior through provoking

images which may act as powerful drivers of behavior, especially when an individual is depressed and having suicidal thoughts.

There has been increasing concern about Internet sites dealing with suicide and their potential negative influence on adolescent suicidal behavior (Collings *et al.*, 2011). The provision of interactive experiences and the development of “online communities” mean that the Internet may have a unique role in influencing suicidal behavior and/or providing peer support and possibly helping prevent suicidal behavior (Daine *et al.*, 2013). Some researchers have highlighted the increased risk that may be associated with Internet use, especially sites that promote suicide methods (Biddle *et al.*, 2008) and also social networking sites (Dunlop *et al.*, 2011).

Few studies have been conducted in this area. In a large community study, depressed young people, especially boys, were heavier users of the Internet, more likely to access the Internet at school, and more likely to use chat rooms and interact with peers they saw infrequently in person, and also strangers (Ybarra *et al.*, 2005). A study of online postings to message boards focusing on self-injurious behavior by young people aged 12–20 years suggested that online interactions provide important social support to users. However, these interactions may also normalize or encourage self-injurious behavior (Whitlock *et al.*, 2006; Daine *et al.*, 2013). The Internet may also provide considerable opportunities for suicide prevention. For example, 6 months after a school-based presentation promoting the use of a website for young people experiencing emotional difficulties, 45% of students said they had visited the website (Nicholas *et al.*, 2004).

While concern has been raised about the possible influence of music (especially certain types of popular music) on suicidal phenomena among children and adolescents, this has received very limited attention in the research literature.

Availability of means for self-harm/suicide

Whether or not a young person engages in self-harm will be influenced by availability of acceptable methods to use. The danger or relative lethality of available methods will also strongly influence the outcome (i.e., whether death is more or less likely). Children and adolescents who die by suicide in the United Kingdom are most likely to have used hanging or self-poisoning.

Suicide is more likely where dangerous means such as firearms (Brent *et al.*, 1991) or pesticides (Eddleston *et al.*, 2005b) are readily available. A major current concern is the increase in hanging or other means of self-suffocation seen in young people of both genders in many countries. Hanging is a readily accessible method as well as having a high rate of lethality (Hawton *et al.*, 1999a). The reasons for the spread in acceptability of hanging and the increased use of this method are not known, but the fact that it is happening in many countries suggests a universal influence, with media portrayal of suicide being a likely candidate (Biddle *et al.*, 2013).

Outcome following self-harm

Repetition of self-harm

Some young people who harm themselves do so on only one occasion. However, during adolescence, many repeat the behavior, often on several occasions. Self-harm that is repeated in adolescence usually ceases by early adulthood (Moran *et al.*, 2012). Persistence is more likely in females than males. Conceptually, the first act of self-harm is different from all those that follow it in that once an adolescent has actually engaged in self-harm, s/he crosses an important behavioral threshold. This seems to reduce the barriers to subsequent self-harm, both nonfatal and fatal. Thus a history of previous self-harm increases the risk of future acts in both clinical and general populations (Gould *et al.*, 2003; Evans *et al.*, 2004). The greatest risk of repetition is in the first year following self-harm, especially the first few months.

Risk estimates for self-harm repetition that involves representation to hospital are between 5% and 15% per year (Bridge *et al.*, 2006), but these are likely to be under estimates as they exclude self-harm which did not receive clinical attention. The risk of repetition remains high for many years after an episode of self-harm. For example, in a 10-year follow-up, Gibb *et al.* (2005) reported that 28% of those admitted for a suicide attempt had been readmitted, with the highest risk in the first 2 years. Repetition rates appear to be similar in the two genders (Gibb *et al.*, 2005; Hawton *et al.*, 2012a).

Depression is a key factor associated with repetition of self-harm in adolescents (Hawton *et al.*, 1999b). Self-reported self-harm at age 12 years predicts suicidal ideation and self-harm at 15 years (Sourander *et al.*, 2006a). Concerns about sexual orientation, history of sexual abuse, family self-harm, anxiety, and self-esteem are also associated with short-term self-harm repetition (O'Connor *et al.*, 2009a). In one study, self-harm in adolescents ceased within 3 years, but those who continued to self-harm into adulthood were characterized by higher rates of psychopathology and adversity in both childhood and adulthood (Harrington *et al.*, 2006); and, in a further study, by anxiety, at least for females (Rudd *et al.*, 2004).

Suicide following self-harm

Follow-up of adolescents who self-harm and present to hospital suggests that the risk of suicide is low in under-15-year-olds (Hawton & Harriss, 2008; Hawton *et al.*, 2012a). However, in older adolescents the risk increases considerably. It is greater in males than females, in those who are repeaters of self-harm and, importantly, in those who cut themselves compared to those who take overdoses (Hawton *et al.*, 2012a). The last point is contrary to the beliefs of many clinicians. The method used for suicide is usually different to the method used for self-harm, death often being due to hanging, at least in the United Kingdom (Hawton *et al.*, 2012a). The risk of suicide following self-harm which does not result in clinical attention is not known.

A history of self-harm is one of the most powerful and clinically relevant predictors of eventual suicide. Most studies find elevated risk of overall mortality following self-harm (Goldacre & Hawton, 1985; Suominen *et al.*, 2004; Gibb *et al.*, 2005). In one follow-up study of 15- to 24-year-olds who had presented to hospital following an episode of self-harm, the overall number of deaths from all causes was 3%, four times higher than expected. This was mainly because of an excess number of suicides (2%), which were 10 times more frequent than expected. The main risk factors for suicide were male gender, previous self-harm, prior psychiatric history, and high suicide intent (Hawton & Harriss, 2007).

Psychosocial adjustment

Aside from repetition of self-harm and occurrence of suicide we know relatively little about the overall outcome of adolescents who self-harm, especially in terms of psychosocial adjustment, describe poor problem solving, impaired peer relationships, and repeated separations in later life for young people who had presented to services following self-harm in adolescence. However, such a negative outcome is certainly not the norm. In an early study of 50 consecutive self-harm patients who presented to a general hospital, those who were classified as having “acute” problems were nearly all doing well even after only a month, whereas many of those with longer term problems, especially if combined with behavioral problems, were doing less well in general after a month (Hawton *et al.*, 1982). In a long-term follow-up of adolescents who took overdoses and then participated in a randomized controlled trial of a brief family intervention (Harrington *et al.*, 1998), after 3 years 70% of the patients were no longer self-harming. Half had used adult mental health services (especially for depression), and among those who continued to self-harm in adulthood, childhood adversity (e.g., sexual abuse) was prevalent and psychiatric disorders, especially depression, common (Harrington *et al.*, 2006). In a Norwegian follow-up study the majority of those who self-harmed as adolescents experienced depressive, anxiety, or personality disorders 8–10 years later (Groholt & Ekeberg, 2009).

Impact of suicide on peers, school and relatives

While there is recognition that self-harm can have a contagious quality in that exposure to self-harm by peers is one of the most important factors associated with adolescents starting to self-harm (Hawton *et al.*, 2002), little is known about other impacts of self-harm on peers. School staff often react with a sense of panic to discovering that pupils are self-harming. Helpful guidance for schools on how to deal with self-harm is available (Hawton *et al.*, 2006). An important but often neglected aspect of self-harm by children and adolescents is the impact this has on their families. There has been little research on the nature, duration, and significance of effects on parents

and other carers. Wagner and colleagues (Wagner *et al.*, 2000) in the United States showed that parental reaction to suicidal behavior may include anger, fear, sadness, and frustration, with parents being intimidated by the intensity of suicidal behavior. They may adopt greater restrictiveness in parenting styles, or alternatively abandon responsibility for their child to someone else. How parents respond may depend on the degree of suicidal intent involved in the act and whether self-harm was the first episode or repeat (Wagner *et al.*, 2000). In a pilot study in Ireland a group support program for parents and carers of young people who had self-harmed seemed to reduce their distress and increase satisfaction with care (Power *et al.*, 2009).

Clinical assessment

All young people who express suicidal thoughts or harm themselves should receive a psychosocial assessment (American Academy of Child and Adolescent Psychiatry, 2001; National Collaborating Centre for Mental Health, 2004, 2011). This should be focused on identifying problems, risk, protective factors, mental illness, and gaining an understanding of the suicidal process for the individual concerned. Assessment can also form a therapeutic intervention in itself. It is extremely difficult for clinicians to predict accurately the risk of their patient dying by suicide or of engaging in nonfatal suicidal behavior, so risk management rather than quantification should be the priority. A psychosocial assessment should form the basis of future clinical management and establishing treatment goals. In adults, having an assessment has been associated with reduced rates of repetition (Bergen *et al.*, 2010; Kapur *et al.*, 2013b). The fact that many adolescents spend very little, if any, time planning their self-harm (Rodham *et al.*, 2004), and that being intoxicated is often associated with many such acts, compounds this issue (Esposito-Smythers *et al.*, 2010). A core task of an assessment is to establish an interactive and dynamic therapeutic relationship and to be part of a response to the young person's distress that offers some hope for a better future.

The assessment of children and adolescents following self-harm is influenced by a range of process and service issues. At a process level, the assessment of adolescents can present particular challenges, as young people are often ambivalent about their suicidality and fluctuating mood states can make it difficult to get clear information, particularly retrospectively. Current guidelines emphasize standards of care and note that several studies have suggested that some staff responsible for medical care have, or are perceived by self-harm patients as having, negative attitudes toward those who harm themselves (Saunders *et al.*, 2012). They may also not recognize the complex relationships between self-harm and mental illness (Friedman *et al.*, 2006). Poor continuity of care requiring frequent repetition of their "story" (Dower *et al.*, 2000) and negative expectations about postdischarge therapy (Rotheram-Borus *et al.*, 1996) contribute to dissatisfaction among some adolescents who have

self-harmed. In a study of adolescent self-harm patients, those who were more satisfied with hospital management and subsequent therapy appeared to have better therapeutic outcomes (Burgess *et al.*, 1998).

In recent years there has been a drive toward the use of screening tools to help guide management. While these may be helpful in reminding clinicians about relevant risk factors, their predictive power is very low and they should not be used as an alternative to psychosocial assessment (National Collaborating Centre for Mental Health, 2011).

The content of a full psychosocial assessment is outlined in Table 64.2. An adjunct to standard assessment has recently been developed with the aim of improving patient attendance and engagement with treatment. Specifically, Ougrin and colleagues (Ougrin *et al.*, 2011) have developed and evaluated a tailored therapeutic manualized assessment approach to adolescents who have self-harmed, in which, following a standard psychosocial assessment, the assessing clinician and the adolescent jointly construct a diagram depicting roles in relation to other

Table 64.2 Areas to cover during psychosocial assessment of adolescents who have self-harmed.

History of recent difficulties
Circumstances of the self-harm (before, during, and after)
Alcohol (had it been consumed?) within 6 hours, at time of attempt (i.e., as part of the act)
Motives/reasons for self-harm
Suicidal intent
Other motives/reasons
Evidence of preplanning
History of previous self-harm
Exposure to self-harm/suicide by others
Media influences—looking at Internet, Facebook, and so on
Psychiatric history
Physical health
Family background
Family history, including self-harm and suicide
Personal and social history and current social circumstances
Interpersonal relationships
• Bullying (including cyberbullying)
• Abuse (physical, sexual, and emotional)

Table 64.3 Major components of the Therapeutic Assessment.

- 1 Take standard psychosocial history and assessment
- 2 Take 10-min break
- 3 Jointly construct a diagram (based on cognitive analytic therapy) which consists of three elements
 - (a) Identification of reciprocal roles
 - (b) Identification of the “core pain”
 - (c) Identification of the maladaptive procedures
- 4 Identify the target problem
- 5 Assess motivation for change and employ motivational interviewing techniques if required
- 6 Search for ways of breaking the previously identified vicious cycles (“exits”), using a range of cognitive (e.g., future-oriented reflexive questioning) and behavioral (e.g., relaxation) techniques, as appropriate
- 7 Summarize the above issues in an understanding letter

Source: Adapted from Ougrin *et al.* (2010).

people, core pain, and “maladaptive procedures,” identify a target problem and potential ways of breaking vicious circles that have been identified, and then describe the diagram and exits in an “understanding letter,” which is shared with the family (see Table 64.3). The therapeutic assessment aims to develop a joint understanding of the difficulties experienced by the young person, to increase motivation for change, to instill hope and to explore alternatives to self-harm (Ougrin *et al.*, 2010). In a randomized controlled trial, adolescents receiving this enhanced assessment were considerably more likely to attend for treatment and to have a greater number of treatment sessions than those who had standard assessment only. There were, however, no differences in measures of psychosocial assessment at follow-up (Ougrin *et al.*, 2011).

Treatments for adolescents who have self-harmed

In a substantial number of adolescents, the crisis associated with self-harm may resolve quite quickly and only supportive care for the adolescent and their family will be required. However, many adolescents will need more intensive therapy, especially in view of the poor longer term outcomes found (as described earlier). There have been surprisingly few randomized evaluations of treatments for children and adolescents who have harmed themselves.

Brief psychological therapy

Problem-solving/cognitive behavior therapy, delivered over 2–10 treatment sessions, appears to be effective in adults in terms of reducing repetition of self-harm and also improving other outcomes compared with treatment as usual (National Collaborating Centre for Mental Health, 2011). Currently, however, there is no evidence of benefits of this with adolescents.

Family therapy

Given the high incidence of family problems in adolescents who self-harm, family therapy, which focuses on the relationships, roles and communication patterns between family members (see Chapter 39), would seem a logical treatment approach for adolescents who self-harm. In a trial in which a brief structured home-based intervention with adolescents who had self-poisoned and their families was compared with treatment as usual, after treatment the nondepressed adolescents in the home-based group had less suicidal ideation than controls, but the home-based intervention was no more effective for depressed adolescents (Harrington *et al.*, 2000).

Group therapy

Group therapy approaches are often used in child and adolescent mental health services. In a preliminary trial in the United Kingdom in which 63 adolescents with a history of repeated self-harm were assigned to group therapy plus treatment as usual (TAU) or TAU only, although there was no apparent effect on depression, group attendees were less likely to repeat self-harm, used fewer routine services and had better school attendance than those who received TAU (Wood *et al.*, 2001). In a similar study in Australia, however, adolescents assigned to the group therapy condition actually repeated self-harm more than those in the control group (Hazell *et al.*, 2009). Finally, in an elegant large-scale trial in the United Kingdom, no differences in outcome were found on a range of measures between those assigned to group therapy plus TAU compared to those in the TAU group (Green *et al.*, 2011). The contradictory results of the first two studies and the definitive negative findings in the much larger third trial probably indicate that group therapy is not a useful approach in this population.

Dialectical behavior therapy

Dialectical behavior therapy (DBT) is a therapeutic approach that focuses on the management of emotional states and interpersonal relationships and which was originally developed for adults with borderline personality disorder and repetitive self-harm. There is growing interest in using this approach in briefer format with adolescents who are multiple repeaters of self-harm, with promising initial results (James *et al.*, 2008).

Hospitalization

The decision to treat adolescents following self-harm in an in-patient setting is usually based on risk of further self-harm and suicide, and severity of psychiatric disorder (Olfson *et al.*, 2005). It may also be influenced by other factors including concerns about litigation, characteristics of the individual and their family (Spooren *et al.*, 1997), the experience and training of the mental health clinician (Morrissey *et al.*, 1995), and the availability of in-patient beds.

However, there is no evidence to suggest that hospitalization prevents young people, particularly those with prior self-harm, mood disorder, and substance abuse, from future self-harm

or dying by suicide (Gould *et al.*, 2003). Furthermore, prior hospitalization for any injury, not just self-harm, is associated with increased risk of suicidal behaviors (Agerbo *et al.*, 2002; Bridge *et al.*, 2006), although this may be related to severity of psychopathology and other risk factors.

Two studies have attempted to address these issues. In the first, conducted in the United States, 289 adolescents were randomly allocated to receive social network intervention plus TAU, or TAU alone, following psychiatric hospitalization. There was a reduction in suicidal ideation and parent-reported functional impairment at 6 months follow-up in those assigned to social network intervention, but no effects on repetition of self-harm or emotional symptoms (King *et al.*, 2006). In the second study, 286 adolescents were assigned to rapid response outpatient follow-up or TAU following presentation to an emergency department in Canada. The results showed psychiatric hospitalizations can be prevented using the rapid response model of care (Greenfield *et al.*, 2002).

Treatments for adolescents with specific psychiatric disorders

Further information about reducing suicidality in adolescents comes from studies of treatment focused specifically on individuals with psychiatric disorders.

Medication

Chapter 63 reviews the debate about the use of antidepressant medications in the treatment of children and adolescents with depression and the question of whether selective serotonin reuptake inhibitors (SSRIs) increase the risk of suicidal behaviors in some young people. It supports the position of the American Academy of Child and Adolescent Psychiatry that SSRIs should be available for selected cases. There do not appear to have been any trials in which medication has been evaluated in the treatment of adolescents who have self-harmed.

Cognitive behavior therapy combined with antidepressant

Cognitive behavior therapy (CBT) is the principal treatment for adolescent depression and affective disorders and targets depressive thoughts and behavior patterns (see Chapters 38 and 63). In a large randomized controlled trial, 439 patients aged 12–17 with major depressive disorder (MDD) were randomly allocated to one of four treatment conditions, each lasting 12 weeks: (i) Fluoxetine alone; (ii) CBT alone; (iii) CBT with fluoxetine; or (iv) Placebo. The CBT treatment consisted of 15 × 1 hour sessions. Patients treated in all conditions showed a reduction in suicide ideation across the trial, those treated with CBT plus fluoxetine showing the greatest improvement (March *et al.*, 2004). However, in two similar trials, CBT combined with an SSRI antidepressant was not superior to the antidepressant alone with regard to suicidality (Melvin *et al.*, 2006; Goodyer *et al.*, 2007).

Multisystemic therapy

Multisystemic therapy (MST) was developed to treat delinquent youth, targeting the systems in which the young people live. MST includes parenting skills, family therapy and educational attainment. In a randomized controlled trial, young people aged 10–17 were assigned to MST or hospitalization following a psychiatric emergency. MST was significantly more effective in reducing youth-reported repetition of suicide attempts (Huey *et al.*, 2004).

Issues of access to treatment and engagement in treatment

Whereas many adolescents may be offered care following an episode of self-harm, only small proportions are successfully engaged in ongoing treatment. Treatment retention for nonhospitalized adolescents is generally below 50% (Van Heeringen *et al.*, 1995; Brent, 1997), and can be as low as 20%, with significant and rapid dropout from treatment (King *et al.*, 1997).

Several studies have investigated mechanisms to improve effectiveness of treatment, including green-card passes to admission to hospital (Cotgrove *et al.*, 1995), enhanced emergency department protocols (Rotheram-Borus *et al.*, 2000; Spirito, 2002), enhanced CBT interventions (Rotheram-Borus *et al.*, 1994), and skills-based interventions (Donaldson *et al.*, 2005). However, to date such efforts have largely been unsuccessful and new therapeutic approaches need to be developed and evaluated (Burns *et al.*, 2005; Ougrin *et al.*, 2012).

Many young people who engage in self-harm do not seek help for their problems. If they do, it is most likely to be from friends and family rather than professionals (De Leo and Heller, 2004; Hawton *et al.*, 2006). There are also gender differences, with distressed young men being less likely to seek help of any kind and those who seek help from their general practitioner (GP) showing more severe symptoms than their female counterparts when they do (Biddle *et al.*, 2004). High school students at highest risk of suicide were found to be more likely to endorse isolative coping strategies such as believing you should be able to sort out your problems on your own and less likely to endorse strategies such as getting advice from friends (Gould *et al.*, 2004).

Prevention of self-harm and suicide by children and adolescents

Approaches to prevention can be divided into those measures that focus on a specific group, for example those with depression (at-risk populations), or measures that target all young people (population-based measures).

School-based interventions

School-based interventions take different forms, including skills-training, gatekeeper training, and screening programs,

as well as whole-school approaches (Lake & Gould, 2011). Prevention programs that are aimed at students as helpers, not as victims, are based on evidence that adolescents turn to their peers for support rather than discussing their problems with adults (Beautrais *et al.*, 1998; Hawton *et al.*, 2006). This approach often raises concerns that not all peer confidants communicate with adults about friends whose problems cause them particular concern (Bennett *et al.*, 2003) and that young males in particular do not respond to troubled peers in helpful ways (Kalafat *et al.*, 1993; Hazell & King, 1996). In recent years, there has been growth in skills-based programs in schools, targeting the development of problem solving, coping, and cognitive skills (Gould *et al.*, 2003). Such classroom-based training offers some promise, as it has been associated with improved coping with distress and a reduction in suicide ideation (Thompson *et al.*, 2001), but caution is required as it may be associated with reduced school connectedness and increased high-risk behaviors (Cho *et al.*, 2005). Culturally specific skills-based interventions have also been developed (Lafromboise & Lewis, 2008). A school-based gatekeeper training program in the United States called Signs of Suicide showed fewer suicide attempts in the intervention group compared with controls, and a modest improvement in students' knowledge and attitudes about depression and suicide. However, no improvement in help-seeking was observed (Aseltine & DeMartino, 2004; Aseltine *et al.*, 2007). A randomized controlled trial of a school-based depression prevention program also showed positive results (Merry *et al.*, 2004).

Case-finding strategies have been employed in some schools, particularly in the United States, in an effort to reduce suicide by early detection of young people at high risk (Scott *et al.*, 2010). Although there is some evidence that screening programs can be effective at identifying at-risk young people (Scott *et al.*, 2009), they place considerable burden on school resources, yield false positives, and given the fluctuating nature of suicidal ideation, one-off screening can also give rise to false negatives (Lake and Gould, 2011; Hawton *et al.*, 2012c). Engagement in treatment following identification remains a significant issue (Shaffer & Craft, 1999; Shaffer & Pfeffer, 2001). Data from the Colombia Teen Screen program indicates that 19% of "at risk" young people refused a referral, 25% did not attend the first appointment, and 17% attended one session only (Shaffer, 2003). There are also difficulties with some schools accepting this approach for various reasons, including lack of staff resources and concerns that asking students about suicide will give them ideas about harming themselves. However, in a randomized controlled trial, depressed adolescents and previous attempters reported lower levels of distress and suicidality following a screening questionnaire that included specific questions about suicidal behaviors compared with their counterparts who were not asked those questions. This study also demonstrated that asking about suicide does not "put the idea into a young person's head" for those who would not ordinarily be thinking about this issue (Gould *et al.*, 2005). Finally, whole-school approaches are likely to be important as they "set the tone" for a school, and

they can change the school ethos around mental health but, as yet, their effect on reducing suicide is yet to be established. An obvious difficulty with any school-based program is the fact that high-risk individuals, particularly school dropouts and those with high rates of absenteeism, will not be reached using this approach (Burns & Patton, 2000).

Reducing access to methods of suicide

The strategy of restricting access by the general population to certain methods of suicide is a widely practiced public health initiative and an effective method of preventing suicide (Hawton, 2005).

In most studies, this results in an overall reduction in suicide deaths. Methods of suicide used by young people vary significantly across different countries. Where self-poisoning with medication is common, reducing availability through restricting pack sizes may be effective (Hawton *et al.*, 2013a). Restricting access to firearms has been a significant focus of suicide prevention in the United States (Brent, 2001), Austria (Etzersdorfer *et al.*, 1992), and Canada (Littman, 1983). Because of the extensive problem of suicide by pesticide ingestion in rural areas of developing countries, prevention of suicide by safer storage of products is also receiving attention (Pearson *et al.*, 2011).

Crisis centers and hotlines

Crisis centers and hotlines offering direct counseling or links to mental health services are conceptually popular. Overall, research suggests that such services tend to be used by young White females, with less impact on young men (de Anda & Smith, 1993). In one US study, high school students had more negative attitudes toward hotlines when compared to other formal sources of help (Gould *et al.*, 2006). The most common reasons for nonuse related to feelings of self-reliance and shame. Beautrais *et al.* (1998) reported that 14% of serious suicide attempters had used a telephone crisis line in the year prior to their attempt. There is little evidence of beneficial effects on rates of suicide (Burns & Paton, 2000), although this would be difficult to demonstrate.

Internet sources of help

Because of the hugely increased use of the Internet and other electronic means of communication, especially by young people, attention is focusing on the use of the Internet, social media, and mobile phones as means of providing help for distressed adolescents (Pirkis & Norderntoft, 2011). While this method of help provision is in its infancy, it is likely to be a major source of support and help for young people in the future, including those not in contact with clinical services.

In view of the negative influences of the Internet and other media, voluntary national guidelines for media reporting have been formulated. Website optimization, whereby sites committed to provision of help appear high on sites accessed in relation to distress or suicidal ideation, may be helpful. National

governments need to continue to work with Internet service providers to this end.

Conclusions, future clinical and research directions

In recent years, considerable advances have been made in understanding the prevalence, causes, and course of adolescent suicidal behavior and self-harm. There is general consensus that good clinical management requires a comprehensive and compassionate approach to clinical assessment and this assessment should take into consideration psychiatric, psychological, social, and cultural factors. Despite the welcome advances in identifying those at risk, a number of clinical and research challenges remain. The evidence base in respect of what works to reduce self-harm or prevent suicide remains weak. Moreover, little is known about how best to respond to different subgroups of young people at risk (e.g., those with high vs low suicidal intent). Also, given the growth of new media and the powerful effect of such social influences on the enactment of all forms of self-harm, a more in-depth understanding of how these factors increase the occurrence of self-harm and suicide is urgently required.

Acknowledgment

The authors thank Sarah Fortune for her very substantial contribution to the preparation of this chapter in the previous edition of the book.

²National Conduct Problems and National Adoption and Fostering Services, Maudsley Hospital, London, UK

Introduction

Oppositional defiant and conduct disorders (ODD/CDs) are characterized by antisocial behaviors outside socially acceptable norms that violate other people's expectations or rights. The behaviors include excessive verbal and physical aggression, temper tantrums, lying and stealing, disobedience, rule breaking, and violence. As adults, many of these individuals continue to act antisocially, with substance misuse and criminality being common. The upset, disruption, and costs inflicted on the family, peer group, school, and wider society are usually considerable. However, perhaps because these behaviors are present in many children to some extent, are often related to a less than ideal upbringing, and may appear to reflect poor self-control in children who seem otherwise normal, ODD/CDs are still considered by some not to be "true" psychiatric disorders but more as character flaws, with the children being seen as nasty and bad. This is unfortunate for several reasons. First, in recent years there have been many exciting discoveries about what contributes to the development of ODD/CDs, with a substantial biological component involving genetic and brain differences becoming evident, so that in many cases the problems are not just due to poor socialization. Second, different subtypes of antisocial behavior are now better understood, with, for example, very different life trajectories for those who exhibit early versus later onset, and those who have callous-unemotional traits. Finally, there have been considerable advances in developing effective treatments not only for children but also for adolescents, who were previously often thought of as virtually untreatable. Now that we know more about the biological and social factors that cause ODD/CD, the seriousness of its consequences and cost, and that effective treatments are available, there is a strong case to be made that children suffering the condition do indeed suffer from a true psychiatric disorder and so deserve proper evaluation and effective treatment. See also Chapter 4.

In this chapter, the term *antisocial behavior* will be used as a broad overarching dimensional construct, with the term ODD/CD used to refer to the more severe end that meets diagnostic criteria; less severe difficulties may be called *conduct problems*. Outside psychiatry, many medical practitioners, mental health professionals, social workers, teachers, and the general public are not familiar with the terms ODD or CD, so that using expressions such as antisocial behavior or disruptive behavior may improve communication. The term externalizing is not used in this chapter since it connotes that an inner angst is being acted out, for which there is usually no evidence. The term children is used to cover both children and adolescents collectively.

Classification

Both ICD 10 and DSM-5 include ODD/CD which are characterized by a repetitive and persistent pattern of antisocial behavior; occasional isolated acts do not qualify. Oppositional Defiant Disorder is usually a diagnosis given to younger children, while Conduct Disorder is typically (but not exclusively) a diagnosis given to older children and teenagers. The criteria are almost identical in the two systems.

Oppositional Defiant Disorder requires four of the following eight symptoms below to be present for at least 6 months, in a manner that is outside a range that is developmentally normative: *angry and irritable mood*: has unusually frequent or severe temper tantrums; is often touchy or easily annoyed by others; is often angry or resentful; *argumentative and defiant behavior*: often argues with adults; often actively refuses to comply with adults' requests or defies rules; often deliberately does things to annoy other people; often blames others for his or her own mistakes or misbehavior; *vindictiveness*: is often spiteful or resentful. Both DSM-5 and ICD 10 include specifiers for degree (mild, moderate, or severe). ICD 10 allows up to 2 of 4 symptoms to

come from the CD list (below); unlike for CD, there is an impairment criterion: the symptoms must be maladaptive. In DSM-5, a diagnosis of CD no longer excludes ODD.

Conduct Disorder requires three of the following 15 criteria to have been manifest in the past 12 months: *aggression to people and animals*: frequently bullies others; frequently initiates physical fights; has used a weapon that can cause serious physical harm to others; exhibits physical cruelty to other people; exhibits physical cruelty to animals; commits a crime involving confrontation with the victim; forces another person into sexual activity; *destruction of property*: deliberately sets fires with a risk of causing serious damage; deliberately destroys the property of others; *deceitfulness or theft*: has broken into someone else's house, building, or car; often lies to obtain goods or favors or to avoid obligations; has stolen objects of value without confronting the victim; *serious violations of rules*: often stays out at night despite parental prohibitions, beginning before age 13; has run away from home at least twice; is frequently truant from school, beginning before 13 years of age. Both DSM-5 and ICD 10 include specifiers for child or adolescent onset and degree (mild, moderate, or severe). ICD 10 includes specifiers for socialized/unsocialized CD, and confined to the family context. DSM-5 includes specifiers for "with limited prosocial emotions" (callous-unemotional traits); there must be impairment; there is no age bar, but antisocial/dyssocial personality disorder (ASPD) criteria should not be met.

There are some differences between the systems: first, in ICD 10, ODD is a subtype of CD, whereas in DSM-5 they are separate entities. This reflects a wide ranging debate. In terms of external validating criteria there are many similarities between the two conditions, with progression from one to the other being not infrequent so that on these grounds they can both be seen as age-related progressions of a cluster of symptoms characterized by antisocial behavior. Because most children with CD also have ODD, DSM-IV did not allow both to be diagnosed at the same time, but this bar has been removed in DSM-5. However, as discussed below, children with the angry and irritable mood symptoms of ODD are more likely to develop mood disorders later in life and to have relatives with mood disorders.

Second, while the ICD 10 *research criteria* are very similar to DSM-5, with both using a menu counting approach to the number of symptoms, ICD 10 also has *clinical guidelines* that are broader descriptions for everyday diagnostic practise. They state, with respect to symptom categories "Any one of these categories, if marked, is sufficient for the diagnosis" (p. 267). An enduring pattern of behavior should be present, but no time frame is given. Third, DSM-5 requires distress or impairment, whereas ICD 10 does for ODD but, confusingly, not for CD. In practise this does not make a lot of difference, since about 80% of those diagnosed with CD have significant impairment (Angold & Costello, 2001; Romano *et al.*, 2001).

Fourth, DSM-5 has two other disorders that may overlap: one that was present in DSM-IV, Intermittent Explosive Disorder (which can only be diagnosed after the age of six) and a new

disorder, Disruptive Mood Dysregulation (DMD) Disorder. DMD has been introduced explicitly to stop overdiagnosis of childhood bipolar disorder and consequent over medication; however, while this form of irritability is now being extensively researched, there would appear to be considerable overlap with ODD, (odds ratio 50–100, Copeland *et al.*, 2013) and the validity of this diagnostic category has not been established. Fifth, DSM-5, like DSM-IV, specifically allows both ODD and CD to be diagnosed in adults; they are nested in the section on disruptive disorders. While there is no stated age cutoff in ICD 10, ODD and CD appear in the disorders "with onset usually in childhood or adolescence" suggesting they may be less applicable in adults. Applying a diagnosis in adults would mean that many people with criminal records can be diagnosed with CD, but neither DSM-5 nor ICD 10 makes reference to the likely consequences; clinicians, epidemiological surveys, and treatment trials do not usually apply the term to adults. Sixth, DSM-5 freely allows multiple diagnoses, whereas ICD 10 prefers wherever possible one diagnosis to be paramount. To help this, it has two categories—hyperkinetic conduct disorder and depressive conduct disorder—to handle two of the commoner coexistent conditions.

Epidemiology

Overall prevalence

The overall prevalence of ODD and CD together varies between 5% and 10% or more according to which survey is cited, and this in turn depends on the methods used and the locality studied. In younger children ODD is commoner than CD, in adolescents the opposite holds. However, there is fairly good agreement on rates of 5–8% in general longitudinal surveys where multi-informant methods that include careful interviews or assessments by a clinician are carried out, as for example in the Christchurch (Fergusson *et al.*, 2005) and Dunedin (Moffitt, 1993) studies in New Zealand, the British Office of National Statistics survey (Green *et al.*, 2005), and the Great Smoky Mountains Study (Costello *et al.*, 2003a). Unsurprisingly, higher rates are found if lifetime prevalences are used, as for example in the National Comorbidity Study Replication (Nock *et al.*, 2006, 2007). Adding an impairment criterion only reduces rates by around 20% to 40% (Angold & Costello, 2001; Romano *et al.*, 2001). Typically, ODD/CD makes up about half of all child and adolescent psychopathology and is the commonest condition.

Variations in prevalence

Gender

Gender, along with quality of parenting, is the strongest predictor of antisocial behavior in most studies (Odgers *et al.*, 2012). Boys outnumber girls by about 2:1 in younger children with ODD, but this ratio goes up for CD in adolescents to be between 3:1 and 7:1. This is partly due to using research criteria, so that for example forcing another person to have unwanted sex, using

a weapon, breaking into a house are far commoner among boys, whereas if general ICD 10 clinical criteria are used, behaviors that can be considered toward diagnosis include severe relational aggression, serious rule breaking with frequent use of alcohol and drugs, and more girls get included. Although the prevalence rates differ, the manner in which risk factors operate appears to be the same for both boys and girls (Moffitt *et al.*, 2001).

Socio economic status (SES) and geographical area

There is a strong gradient according to socio economic status (SES), thus for example in the ONS survey ODD/CD was five times more common in the lowest SES than the highest. Likewise, rates are typically 2–3 times higher in inner-city deprived areas compared with well-off suburbs.

Worldwide prevalences and minority ethnic groups

Across low, middle, and high income countries, many different rates have been reported, but comparisons are hard as studies have used different methods. However, an important exception to this is the studies that have used the Strengths and Difficulties Questionnaire and the Development and Well-Being Assessment (DAWBA) interviews. Such comparisons find very high rates of ODD/CD in Bangladesh (8.9%), high rates in Yemen (7.1%) and Brazil (7%), medium rates in Britain (5.3%), but low rates in Italy (1.2%), and very low rates in Goa, India (0.4%). In developed countries, among minority groups, there are higher rates among ethnic groups of African Caribbean/African American Heritage; this is not just due to reporting bias or prejudice, insofar as it is upheld by self-report of delinquency. In contrast, there are lower rates among Hispanic Americans in the USA and notably low rates among British Indians (Goodman *et al.*, 2010). The authors suggest the differences are at least in part related to close family structures with clear disciplinary practises at home, a strong emphasis on educational attainment, and cultural values that disapprove of an antisocial lifestyle (Goodman *et al.*, 2010).

High-risk populations

Rates of ODD/CD go up considerably in children who have been maltreated (see Chapter 29), who were brought up in residential care, or have been transferred to foster care (see Chapter 21), children with intellectual disability (see Chapter 54), and, unsurprisingly, in young offenders (Abram *et al.*, 2003; see Chapter 49).

Time periods

Rutter and Smith (1995) showed convincingly an increase in all types of mental health disorder in children over the second half of the twentieth century. Collishaw *et al.* (2004) in a review of three nationally representative studies of teenagers in England from the 1970s until the turn-of-the-century showed roughly doubling in ODD/CD (but no change in rates of attention deficit hyperactivity disorder (ADHD)). Maughan *et al.* (2008) found that this increase seemed to have plateaued out in the

early twenty-first century, using the ONS surveys of 1999 and 2004. Collishaw *et al.* (2012) found no evidence that the earlier increase was related to changes in parenting practices.

Subtypes according to phenomenology and longitudinal course

There have been numerous subdivisions of antisocial behavior using factor analytic techniques on cross-sectional data. They include overt antisocial behavior (tantrums, aggression) versus covert (lying and stealing); proactive aggression (premeditated, predatory attacks) versus reactive aggression (irritable lashing out only when provoked; Polman *et al.*, 2007); physical aggression (hitting, biting) versus relational aggression (bullying, scapegoating, verbal insults) and antisocial behavior at home versus antisocial behavior at school. While factor analysis can produce these distinct subtypes, the problem is that often correlations between items across subtypes are as great as those within (Patterson *et al.*, 1989). Therefore more robust ways of dividing up different antisocial phenomena are needed that are supported by several independent validating criteria cross-sectionally, such as family history, genetic indices (although this criterion is complicated since it is now emerging that similar genotypes can give rise to a wide range of disorders, see Chapter 24), neuropsychological features revealed on psychometric testing or brain functioning, and response to treatment (for more about classification, see Chapter 2).

Categories of antisocial behavior are further strengthened if they predict longitudinal course (Rutter, 2011; see Chapter 4) and this approach has led to important changes of emphasis. Back in 1966, Lee Robins published a classic paper showing that it was not any one particular symptom or symptom group that predicted adult outcome, but rather the severity, diversity and duration of symptoms in childhood. Robins found that roughly 40% of children with conduct problems went on to have significantly impaired, criminal adult lives, but that looking back, 90% of recidivist criminals had had conduct problems in childhood, figures that have been borne out by subsequent research. In the last 20 years, timing of the symptom onset has emerged as a powerful predictor of outcome as noted by Patterson *et al.* (1989). In a classic paper of 1993, Moffitt and colleagues described three different groups from the Dunedin study, “early onset lifetime persistent,” “adolescence limited” and “not antisocial (NA).” While the adolescence limited group had few neurocognitive deficits, and were declining in their antisocial behavior in their early 20s, the early onset group had lower IQ, hyperactivity and inattention problems, poorer memory, greater peer difficulties, and more severe family and psychosocial circumstances.

After this paper, it seemed as if early onset conduct problems would likely presage some fairly dire consequences, whereas the adolescence-limited group would be of less concern. However, there have been two subsequent caveats from this study. First, the adolescence-limited group turned out to continue to offend at moderately high levels into their 30s, and while this

Figure 65.1 Subtypes of antisocial behavior by longitudinal course (data synthesis from several longitudinal studies).

was significantly lower than the rate seen in the early-onset persistent group, it was not trivial, leading to a change in name to “adolescent onset” (Odgers *et al.*, 2008). The same researchers using the same database uncovered an early-onset group who desisted from antisocial behavior, the so-called “childhood-limited” group (Odgers *et al.*, 2007); see Figure 65.1. Broadly speaking, these four groups have been replicated by other researchers (Farrington *et al.*, 2009), and apply to females as well as males (Fontaine *et al.*, 2009) and the hunt is now on to find distinguishing features, especially between early-onset persistent and childhood limited groups. The Dunedin group found that both had similar neurocognitive and psychosocial profiles, but that a family history of criminality or alcoholism predicted persistence (Odgers *et al.*, 2007). In a different population, Barker and Maughan (2009) found that predictors of the early-onset persistent trajectory compared to childhood limited were maternal anxiety during pregnancy, partner cruelty to the mother, harsh parenting, and higher levels of child undercontrolled temperament. Identifying reliable predictors would help planning of effective prevention and intervention services.

Long-term prognosis

Overall, ODD/CD is a condition with markedly poor long-term outcomes, which are summarized in Table 65.1.

While the precise figures vary from study to study, the elevation in risk is considerable. Thus, for example, in the Christchurch study, Fergusson *et al.* (2005) found that the 5% most antisocial children (thus equivalent to a diagnosis of ODD/CD) aged 7 years had, at age 26 when compared to those who were NA as children (50% of the sample) the following comparative outcome rates: violent offending 35% versus 3%, heavy drug usage 20% versus 5%, teenage pregnancy 20% versus 4%, leaving school with no exam qualifications 52% versus 6%, receiving state benefits 33% versus 9%.

Dividing children with ODD into irritable, headstrong, and hurtful predicts different longitudinal outcomes. Those who display more irritable characteristics (angry outbursts and tantrums) are more likely to develop anxiety and depression (but not fears) in the following years, whereas those with headstrong characteristics (defiant and disobedient) are more likely to develop conduct disorder (Stringaris & Goodman, 2009; Whelan *et al.*, 2013; see Chapter 5). The hurtful group (characterized by callous-unemotional traits—see Chapter 68) are more likely to develop aggressive conduct disorder. Generally speaking, children with ODD/CD who also have callous-unemotional traits have a poorer prognosis (Fontaine *et al.*, 2011).

As individuals with ODD/CD get older, offending reduces considerably in their 40s and 50s. However, this does not mean to say that their lives have become satisfactory, thus for example the Cambridge study of delinquent development found that in the late 40s these individuals showed a high rate of “life failure” defined using multiple indices (Piquero *et al.*, 2010).

Health outcomes are also worse, including increased mortality, thus for example in the 1958 British birth cohort, by age 46 mortality was doubled from 1.5% in the least antisocial three-quarters as teenagers to 3% in the most antisocial quarter (Jokela *et al.*, 2009). While this may not seem a large percentage increase, the numbers are very large in total population terms.

Table 65.1 Adult functioning of children who had ODD/CD.

Criminal behavior	More violent and non violent crimes, for example, mugging, grievous bodily harm; theft, car crimes, fraud.
Mental health problems	Increased rates of antisocial personality, alcohol and drug abuse, anxiety, depression and somatic complaints, episodes of deliberate self-harm and completed suicide, time in psychiatric hospitals
Education and training	Poorer examination results, more truancy and early school leaving, fewer vocational qualifications
Employment	More unemployment, jobs held for shorter time, jobs lower status with lower income, increased claiming of benefits and welfare
Social network	Fewer significant friends; friends more likely to be antisocial or in a gang; less constructive joint activities; less emotional confiding. Low involvement with relatives, neighbors, clubs and organizations
Intimate relationships	Increased rate of short lived, violent cohabiting relationships including domestic violence; select partners who are often also antisocial
Children	Increased rates of child abuse, conduct problems in offspring, children taken into care
Health	More medical problems, earlier death

Table 65.2 Factors predicting poor outcome.

Onset	Early onset of severe problems, before age 8
Phenomenology	Antisocial acts which are severe, frequent, and varied; physical aggression; premeditated acts;
Comorbidity	Hyperactivity and attention problems; callous-unemotional traits
Intelligence	Lower IQ
Family history	Parental criminality; parental alcoholism
Pregnancy	Possibly maternal anxiety during pregnancy, smoking
Parenting	Harsh, inconsistent parenting, with high criticism, low warmth, low involvement, and low supervision; interparental violence
Wider environment	Low income family in poor neighborhood with ineffective schools.

The risks were amplified at age 65 follow-up (Maughan *et al.*, 2013) (Table 65.2).

Service use and cost

Both in childhood and in the longer term into adulthood, individuals with ODD/CD are expensive to society. In childhood, they and their families are in contact with multiple agencies. Use of social services is significantly higher than for children with emotional disorders. Utilization of specialist child mental health and social services is significantly higher among children with unsocialized CD than socialized CD (Shivram *et al.*, 2009). Apart from service use, substantial costs fall on the families in terms of lost opportunity to work (Romeo *et al.*, 2006). Over the longer term, by their mid-20s, children who had ODD/CD cost an average 10 times as much as controls (Scott *et al.*, 2001) which in the USA can be as much as \$2 million, once crime victim costs and drug misuse costs are included (Piquero *et al.*, 2013). These high figures mean that good-quality early intervention can be very cost-effective.

Etiology

Below, a number of separate factors are discussed and at the end of this section it is proposed that these need to be combined and evaluated for their contribution to any individual case, along with recognition that over the life course, different influences may hold different sway (see Chapter 1).

Individual-level influences

Overall genetic effects

Whereas a generation ago, antisocial behavior was typically seen purely as a result of poor socialization and voluntarily-determined self-control, it has become clear that for some subtypes, there is a strong genetic contribution. Twin studies have shown substantial genetic influences but also a substantial shared environmental component (Bornovalova *et al.*, 2010). However, this varies according to subgroup. Genetic contribution (see Chapter 24) is higher for antisocial behavior in the

presence of inattention and hyperactivity (Thapar *et al.*, 2013), callous unemotional traits (Viding *et al.*, 2008) or high levels of physical aggression (Burt, 2009) and also if the antisocial behavior is pervasive across situations (Arsenault *et al.*, 2003). Conversely, where these factors are absent, genetic contribution is low (Silberg *et al.*, 1996; Viding *et al.*, 2008).

Specific genes

Main effects of particular genotypes for antisocial behavior, as opposed to ADHD, have not been particularly evident and isolated findings have not consistently been replicated; no consistent linkage regions have been identified (Plomin *et al.*, 2013). One approach has been to look at systems of genes, rather than individual genes. Using this approach, Bentley *et al.* (2013) found eight single-nucleotide polymorphisms that accounted for 16% of the variance within a latent antisocial phenotype. While this is promising, it will need replicating. Genome-wide association studies are in their infancy, one large study found four promising markers; interestingly, none of the top signals resided in traditional candidate genes (Dick *et al.*, 2011). Genome-wide approaches to date have been disappointing for ODD/CD, typically accounting for at most 2% of the variance in a phenomenon. Perhaps in future, with larger samples, better subtyping and more precise methods, more variance will be accounted for, as is the case, for example, for schizophrenia (see Chapter 24).

However, while so far little concrete evidence has been found for main effects, a much-cited paper (Caspi *et al.*, 2002) found that for adult antisocial behavior, there was a gene-environment interaction. A functional polymorphism in the gene for monoamine oxidase A (MAOA), which is widely involved in metabolizing a broad range of neurotransmitters, had no main effect on children, but a form of the gene which is associated with lower MAOA made individuals especially prone to develop antisocial behavior if they had been maltreated. Although attempts to replicate this finding have been mixed, it is supported by a meta-analysis (Kim-Cohen *et al.*, 2006) and by more recent replications (Aslund *et al.*, 2011). A recent line of investigation is the impact of environmental influences on epigenetic processes,

whereby identifiable chemical changes such as acetylation and methylation of genes are affected by the environment (see Chapter 25). Thus for example in human adolescents, a study has shown differentially increased methylation in those whose parents were stressed (Essex *et al.*, 2013). Even if and when substantial specific gene effects are found, it will be important to understand their mode of action, for example how they might modulate neurotransmitter levels and affect reactivity.

Pregnancy and perinatal complications

Several influences during pregnancy have been associated with increased antisocial behavior in children. Thus maternal alcoholism during pregnancy can lead to increased antisocial behavior as part of the fetal alcohol syndrome (see Chapter 23). Its association with ODD/CD would seem likely to be mediated through effects on the brain and subsequent lowering of IQ (see Chapter 23), but alternative mechanisms have not in the main been tested, and high alcohol intake during pregnancy is associated with other sub optimal maternal practises and experiences, so causal effects are hard to disentangle. Smoking is also associated with increases in antisocial behavior, but the mechanisms may be different (see Chapter 23). Animal studies can show the importance of alcohol and smoking in high doses, but in less extreme exposure, the confounding with genetic influences is considerable, and both influences have been argued to have little effect for most human cases of ODD/CD (Thapar & Rutter, 2009; Jaffee *et al.*, 2012). Likewise, while perinatal complications are associated with antisocial behavior, once other factors are accounted for, it is uncertain whether they have any contributory effect (Nomura *et al.*, 2008).

Temperament

Individual differences in infancy that might contribute to subsequent risk of psychopathology were conceptualized by Thomas and Chess in terms of temperament, which they viewed as inherited and not significantly influenced by experience (Thomas *et al.*, 1968). Several prospective studies have shown associations between early temperament and later conduct problems (Keenan & Shaw, 2003). Traits usually identified are negative emotionality, poor emotional self-regulation, inattention, and restlessness. Temperament as originally conceived should be strongly heritable and experience-free. However, measures of temperament are only moderately heritable, and a child's engagement with the social world from birth means that temperament measures inevitably assess the outcome of social processes. It seems probable that as originally conceived by Thomas *et al.* (1968), a "difficult" temperament becomes more likely to lead to disruptive behavior problems when it interacts with a harsh inconsistent parenting style (Bradley & Corwyn, 2008; Bornovaalova *et al.*, 2014).

Brain function

Systems neuroscience studies (see Chapter 10) and brain imaging studies (see Chapter 11) have been far more extensive

for ADHD than ODD/CD, and studies have often conflated the two. Fairchild *et al.* (2011) found lower amygdala volume in both early-onset and adolescent-onset ODD/CD, regions associated with the processing of socio-emotional stimuli; they also found reduced right insula volume in the adolescent-onset subgroup. These differences were maintained after controlling for callous-unemotional traits (which are associated with their own particular brain changes, notably amygdala hypofunction; see Chapter 68) but ADHD was not controlled for. Reviewing neuroimaging literature on brain structure, function, and connectivity in both disorders, Rubia (2011) concluded that ODD/CD is consistently associated with abnormalities of the "hot" paralimbic system that regulates motivation and affect, comprising lateral orbital and ventromedial prefrontal cortices, superior temporal lobes, and underlying limbic structures, most prominently the amygdala. In contrast, ADHD is characterized predominantly by abnormalities in inferior frontal, striatal, parietotemporal and cerebellar regions and networks that mediate "cool" cognitive, that is, inhibitory, attention and timing functions associated with the disorder. There is thus evidence for dissociated underlying pathophysiologies for these two disorders.

Language, IQ, and educational attainment deficits

Low IQ and low school achievement are important predictors of ODD/CD and delinquency. In an English epidemiologic study of twins aged 13 years, low IQ of the child predicted conduct problems independent of social class and of the IQ of parents (Goodman *et al.*, 1995). Conduct disordered children, delinquent adolescents, and adult antisocial individuals show poor performance on standardized tests of verbal ability, and in tests of IQ, poor verbal ability; performance scores are lower too, but usually not as much as verbal ones (Loeber *et al.*, 2012). These associations hold after controlling for potential confounds such as race, socioeconomic status, academic attainment and test motivation (Petersen *et al.*, 2013). Longitudinal studies show that persistence in antisocial behavior over periods of years is predicted by low language ability/verbal IQ in childhood (Petersen *et al.*, 2013). Possible mechanisms may include lower abilities to recall oral instructions and to use language to think through the consequences of actions contributing to the poorer control of actions. Children who cannot reason or assert themselves verbally may attempt to gain control of social exchanges using aggression. Low IQ can contribute to academic difficulties which in turn mean that school becomes unrewarding, rather than a source of self-esteem and support, low school attainment further adds to the probability of ODD/CD developing even after allowing for IQ (Murray & Farrington, 2010).

Executive dysfunction

Children and adolescents with conduct problems have been shown consistently to have poor executive functions. These comprise those abilities implicated in successfully achieving goals through appropriate, effective actions. Specific skills include

learning and applying contingency rules, abstract reasoning, problem solving, self-monitoring, sustained attention, and concentration, relating previous actions to future goals, and inhibiting inappropriate responses. These functions are largely, although not exclusively, associated with frontal lobe function. The meta-analysis by Ogilvie *et al.* (2011) with nearly 15,000 participants found that individuals with externalizing problems had lower scores by an average effect size of 0.54 sd, with significant effects after allowing for comorbid ADHD. Specifically, Fairchild *et al.* (2009) found that children with ODD/CD were more likely to take risky decisions and were less sensitive to punishment. Further, Hobson *et al.* (2011) showed that ODD/CD but not ADHD was related to “hot” executive functioning based on increased risky decision-making in a gambling task. ODD/CD was also independently related to aspects of “cool” executive functioning, independent of ADHD, namely slower speeds of inhibitory responding. These studies implicate reward-related abnormalities in ODD/CD development. Although most studies of executive deficit involve adolescents, such deficits have also been linked with disruptive behaviors in very young preschool children (Hughes & Ensor, 2011).

Autonomic reactivity and the hypothalamus-pituitary-adrenal axis

A low heart rate has been found consistently to be associated with antisocial behavior, and a meta-analysis of 40 studies suggested it is the best replicated biological correlate of antisocial behavior, with the association becoming even stronger during stress tests (effect size 0.76, Ortiz & Raine, 2004); the same group found the association is almost exclusively genetically mediated (Baker *et al.*, 2009). Other psychophysiological indicators of slow autonomic system reactivity have also been examined. Lorber (2004) conducted a meta-analysis and found children with conduct problems had lower skin conductance activity ($d = -0.30$); low levels that predict later antisocial behavior are detectable in infants (Baker *et al.*, 2013). The explanation for the link between slow autonomic activity and antisocial behavior remains unclear. Cortisol secretion data are mixed, with no differences in basal secretion rate in ODD/CD, but some evidence for decreased secretion under stress (Fairchild *et al.*, 2008; Platje *et al.*, 2013).

Information processing & social cognition

Dodge proposed the leading information-processing model for the genesis of aggressive behaviors within social interactions (Dodge, 1993). The model hypothesises that children who are prone to aggression focus on threatening aspects of others' actions, interpret hostile intent in the neutral actions of others (a hostile attributional style), and are more likely to select and to favor aggressive solution to social challenges (response and evaluation decision). Several studies have demonstrated that aggressive children make such errors of social cognition and decision-making (Fontaine *et al.*, 2010).

Family-level influences

Child rearing practises

There is ample evidence that ODD/CD is associated with less than optimal parenting practises, characterized by harsh inconsistent discipline, low warmth and involvement, and high criticism (Rutter *et al.*, 1998). These processes could be, and often are, a response to parents feeling irritated by the behavior of their child. However, Patterson in his classic work *Coercive Family Process* (1982) and subsequent publications showed that parenting could cause and exacerbate antisocial behavior. Parents of antisocial children were found to be more inconsistent in their use of rules, to issue more and unclear commands, to be more likely to respond to their children on the basis of their own mood rather than the characteristics of the child's behavior, to be less likely to monitor their children's whereabouts and to be unresponsive to their children's prosocial behavior.

Several specific mechanisms operate. First, positive overtures and behaviors by children are ignored and so become extinguished. Second, negative behavior attracts parental attention, which even though it is usually critical and hostile, is nonetheless reinforcing where the overall context is one of being ignored. This is one of the central paradoxes in conduct problem families: parental behaviors that are aversive (and so reduce antisocial behavior) when sparingly applied in the context of plentiful warm interactions, become rewarding and promote oppositional and aggressive behaviors when children receive little other attention. Third, there is what Patterson called the negative reinforcement trap: a parent responds to mild oppositional behavior by a child with a prohibition to which the child responds by escalating his behavior and mutual escalation continues until the parent backs off, thus teaching the child that if he gets more aggressive, his parents will back off and he will get his way (Gardner, 1989).

In considering the role of coercive processes in the origins or maintenance of conduct problems, we need to consider possible alternative explanations: (a) that the associations reflect familial genetic liability toward children's psychopathology and parents' coercive discipline, (b) that they represent effects of children's behaviors on parents and (c) that coercive parenting may be a correlate of other features of the parent/child relationship or family functioning that influence child behaviors. Regarding (a), common genetic liability, recent studies using genetically sensitive designs, have shown that for both genetically related and genetically unrelated parents and children, there was a strong association between parent-to-child hostility and child antisocial behavior, suggesting that the effect is not just due to passive genotype-environment correlation (Harold *et al.*, 2013). Regarding (b), child effects on parents, there is considerable evidence that children's difficult behaviors do evoke parental negativity. One experiment observed the interactions of normal and ODD/CD children when with their own parents, the parents of normal children, and the parents of other conduct disordered children (Anderson *et al.*, 1986). ODD/CD children elicited more negative reactions from all groups of parents than

did non-ODD/CD children. Adoption studies (O'Connor *et al.*, 1998) have shown that adoptees at genetic risk of antisocial disorders are more likely than low risk children to evoke negative parenting in the adoptive home.

The role of the child in influencing parental monitoring has also received attention. Stattin and Kerr (2000) pointed out that studies of parental monitoring have generally assessed how much knowledge parents have of their children's whereabouts, but not how parents acquired it. They showed that the majority of this knowledge came from what the child chose to tell the parent, and conduct-problem adolescents told their parents less about what they are doing, again showing child characteristics affecting parenting style. These findings have since been amply confirmed by 47 studies in the subsequent decade (Racz & McMahon, 2011).

The fact that children's behaviors can evoke negative parenting does not however mean that negative parenting has no impact on children's behavior. As well as the cross-sectional observational studies mentioned above, several longitudinal studies indicate that it does. For example, the E-Risk longitudinal twin study showed that with identical twins, those whose mothers were more critical at age 7 had greater antisocial behavior as rated by teachers at age 7, again controlling for initial levels of antisocial behavior. The same study looked at the effects of fathers' parenting on young children's aggression (Jaffee *et al.*, 2003). As expected, a prosocial father's *absence* predicted more aggression by his children. But in contrast, an antisocial father's *presence* predicted more aggression by his children, and his harmful effect was exacerbated the more time each week he spent taking care of the children, thus again suggesting a direct effect independent of any genetic contribution. These and many other studies provide an overwhelming amount of evidence for the contribution of poor parenting practises to antisocial behavior. Regarding (c), that coercive parent-child relationships may only be a marker for other more relationship problems, two leading candidates are attachment insecurity and exposure to interparental conflict; both are discussed below.

Attachment insecurity

Even before he had articulated his theory of attachment in detail, John Bowlby's (1944) study of juvenile thieves implicated their attachment to their parents. Insecure attachment patterns, especially disorganization (see Chapter 6), are fairly strongly associated with antisocial behavior. The meta-analysis by Fearon *et al.* (2010) found an overall effect size of the association of 0.58. These findings are most prevalent in infancy and early childhood, but more recent studies are beginning to address the representation of attachment in middle childhood and adolescence using instruments such as the child attachment interview (Futh *et al.*, 2008; Scott *et al.*, 2011). However, most studies have not been designed to examine whether both attachment insecurity and antisocial behavior are different manifestations of harsh, inconsistent, and frightening parenting. An exception was the study by Scott *et al.* (2011) which examined whether attachment

insecurity in a large and diverse sample of adolescents predicted antisocial behavior once parenting practise had been taken into account; they found that it did.

Exposure to interparental conflict and violence

For some time, studies have shown that children exposed to domestic violence between adults are subsequently more likely to themselves become aggressive (Moffitt & Caspi, 1998). Cummings and Davies (2002) proposed that marital conflict influences children's behavior because of its effect on their regulation of emotion, for example by responding to frightening interparental conflict by down regulating their own emotion through denial of the situation. Cognitively, this may lead to inaccurate appraisal of other social situations and ineffective problem solving; emotionally, it may lead to greater behavioral reactivity to stress. Social learning theory suggests that children's aggression may be increased because they imitate aggressive behavior modeled by their parents and may learn that aggression is a normative part of family relationships which is an effective way of controlling others, and that it is sanctioned, not punished. More studies are needed however, to see the extent to which interparental conflict adds to child antisocial behavior over and above direct parent-child conflict. Results are inconsistent—while some researchers find an additional effect, others find no extra contribution from interparental conflict (Harold *et al.*, 2013).

Maltreatment

Physical punishment is widely used, and parents of children with conduct problems frequently resort to it out of desperation. Overall, associations between physical abuse and conduct problems are well established (see Chapter 29). Links with conduct problems are not, however, straightforward. The risk for conduct problems does not apply equally to all forms of physical punishment. The E-risk longitudinal twin study was able to compare the effects of corporal punishment (smacking, spanking) versus injurious physical maltreatment using twin-specific reports of both experiences (Jaffee *et al.*, 2005). Results showed that children's genetic endowment accounted for virtually all of the association between their corporal punishment and their conduct problems. This indicated a "child effect," in which children's bad conduct provokes their parents to use more corporal punishment, rather than the reverse. Findings about injurious physical maltreatment were the opposite. There was no child effect provoking maltreatment and moreover, significant effects of maltreatment on child aggression remained after controlling for any genetic transmission of liability to aggression from antisocial parents. Little is known about the possible mechanisms linking maltreatment to conduct problems, although threats to security of attachment, difficulties in affect regulation, distortions of information processing and self-concept and failure to model and reward prosocial behavior are likely to be relevant.

Influences beyond the family

Overview of peer effects

As children spend more time outside the family and friends or in education, there are increasing interchanges with other children. Observational studies show that children with ODD/CD have more negative interchanges with other children, across the age range from early childhood up to adolescence, and tend to be rejected by nondeviant peers (Boivin *et al.*, 2013). Three processes could be at work: the child's individual antisocial behavior could lead to peer problems, or vice versa, deviant peer relationships could lead to antisocial behavior, or finally, some common factor could lead to both. Evidence has been found for all three effects.

Peer rejection

Regarding the possibility that conduct problems lead to peer difficulties, there is ample evidence that children with established conduct problems are more likely to have more conflict with peers, and to be rejected by nondeviant peers (Coie, 2004). This peer rejection has been shown to contribute to declines in academic achievement and increases in aggression across the first year of primary schooling (Coie, 2004). One consequence of rejection by healthy peers is that from as young as 5 years, aggressive-antisocial children tend to associate with other deviant children (Boivin *et al.*, 2013).

Impact of deviant peers on antisocial behavior

Regarding the possibility that peers lead to conduct problems, this has been shown to come about in several ways. Youth who are aggressive are attracted to each other, and deviant youth reinforce each others' antisocial behaviors and attitudes (Boivin *et al.*, 2013). Evidence that peer influences do increase antisocial behaviors applies primarily to adolescents. Several longitudinal studies confirm that antisocial young people who have deviant peers offend more, and over and above this, increase their rates of antisocial acts and offending after joining a gang, and reduce it if they leave the gang (Murray & Farrington, 2010). Strong evidence comes from treatment experiments: in two controlled clinical trials, boys treated in groups did worse than untreated controls; treatment was followed by increased adolescent problem behaviors and poorer outcomes (Dishion *et al.*, 1999). After group-level treatment brought the boys together, they mutually reinforced each other's antisocial activities, a finding which argues for individual treatment approaches.

School effects

It is well established that children with ODD/CD are far more likely to attend schools with high delinquency rates, which have high levels of distrust between teachers and students, low pupil commitment to the school, and unclear and inconsistently enforced rules (Graham, 1988). However, it is less clear to what extent the schools themselves influence antisocial behavior,

by their organisation, climate, and practises, or to what extent the concentration of ODD/CD in certain schools is mainly a function of their intakes. In the Cambridge Study, most of the variation between schools in their delinquency rates could be explained by differences in their intakes of troublesome boys aged 11 (Murray & Farrington, 2010). However, reviews of American research show that schools with clear, fair, and consistently enforced rules tend to have low rates of student misbehavior, even allowing for intake levels of conduct problems (Gottfredson, 2001). Thus this type of school climate may act as a protective factor.

Poverty

That antisocial children come in disproportionate numbers from poor families has been repeatedly confirmed; however, several studies show that the effect is indirect, disappearing after controlling for child-rearing practises. Some of the earliest reports showed this; thus the Glueck's study of delinquency found that harsh discipline, low supervision and weak parent-child attachments accounted for the effects of poverty on children's antisocial behaviors in the 1930s (Sampson & Laub, 1994). Many longitudinal studies since then have confirmed this (Murray & Farrington, 2010). Furthermore, reducing poverty can reduce antisocial behavior, as seen in the "natural experiment" described by Costello *et al.* (2003b). Native American families in North Carolina, formerly living below the poverty line, benefited from increased income from newly opened casinos. Overall, children's ODD/CD problems decreased. However, the effect of increased income was mediated through better parent-child relationships. This study suggests that poverty is not simply an epiphenomenon due only to passive correlation, whereby families with worse relationships for various reasons also earn less, but rather that poor circumstances can also affect parenting quality, which in turn affects child antisocial behavior.

Neighborhood influences

Young people with ODD/CD disproportionately live in inner-city areas characterized by physical deterioration, neighborhood disorganization and high residential mobility. However, it is difficult to determine to what extent the areas themselves influence antisocial behavior and to what extent it is merely the case that antisocial people tend to live in deprived areas. Based on comparisons between the rural Isle of Wight and inner London, Rutter (1981) argued that neighborhoods have only indirect effects on antisocial behavior through their effects on individual people and families. In the Chicago Youth Development Study, the relation between community structural characteristics (concentrated poverty, racial heterogeneity, economic resources and violent crime rate) and individual violence was mediated by parenting practises, gang membership, and

peer violence (Tolan *et al.*, 2003). The geographical gradient remains after controlling for SES, and in the study by Odgers *et al.* (2012) was entirely mediated by supportive parenting (high warmth and close monitoring).

Synthesis

The above account has shown that many different factors influence the development of ODD/CD. The question arises how they may operate in the individual case; some but not other factors will be present. A number of points can be made: first, a number of these risks are intercorrelated, and studies that measure several of them often find that once allowed for, some lose their significance. We have seen for example that in several studies, neighborhood effects and SES were entirely mediated through parenting practises, which repeatedly emerge as a major factor. Second, where there are more highly heritable characteristics such as inattention/hyperactivity, lower IQ, and callous-unemotional traits, the prognosis is generally worse. Third, being subject to several risk factors seems to have a cumulative effect so that outcomes exponentially worsen (Van der Laan *et al.*, 2010). This seems likely to be due to interactions between child characteristics, such as temperament, and the environment, whereby for example children with irritable, negative personalities do especially badly when they are brought up in a harsh and inconsistent manner. Thus between childhood and adolescence, children with ADHD are far more likely to develop CD if they are subjected to critical Expressed Emotion (Taylor *et al.*, 1996).

The interaction between child traits and the environment may not always be a negative process; there is emerging evidence that such children do better than more phlegmatic individuals if their upbringing is particularly good, a finding that is beginning to be supported through experimental trial evidence (Scott & O'Connor, 2012). Fourth, as children grow up, their circumstances will change and they will not be passive recipients of their environment, but will to some extent shape their surroundings, partly due to the consequences of having a disorder, and partly due to seeking out more risky environments. This is not just in terms of evoking more negative parenting, but also because genetic predisposition can influence peer processes whereby peer victimization and rejection are more likely (Boivin *et al.*, 2013). Over development, accumulating consequences of this kind make ODD/CD more likely to persist, so that the children remain in high-risk environments and have restricted opportunities for involvement in more positive relationships and roles. However, the counter of this is that those children and adolescents who have more positive experiences are more likely to desist from delinquency and get qualifications and employment, for example if they leave an antisocial behavior group (Sweeten *et al.*, 2013). Paradoxically therefore, those children with the more difficult temperaments and adverse circumstances may respond more to interventions that can make their environments better than children with the same levels of ODD/CD who do not have difficult temperaments.

Assessment, diagnosis, and formulation

Assessment

Before the interview

Because the phenomena of antisocial behavior are so overt, questionnaires are less essential than in some conditions (such as anxiety and depression, where children may reveal symptoms that the parents are unaware of). However, getting both parent and teacher to fill in questionnaires is helpful for a number of reasons. First, it is important to get the perspective of the school. Second, comorbidity can more easily be picked up if a broad symptomatology questionnaire is used, such as the Strength and Difficulties Questionnaire (SDQ; www.sdqinfo.com) or the Achenbach System of Empirically Based Assessment (ASEBA; www.aseba.com). The SDQ is free and shorter, the ASEBA costs and is longer; on the major dimensions they correlate closely (Goodman & Scott, 1999). Domain specific questionnaires such as the Eyberg Child Behavior Inventory (ECBI; www4.parinc.com/Products/Product.aspx?ProductID=ECBI) are useful as a baseline from which treatment effects can be monitored (see Chapter 33). Children tend to underreport their antisocial behavior, so questionnaires below say the age of 11 are usually unhelpful, but by mid-to late adolescence a self-report of delinquent acts becomes more reliable, and typically reveals far more criminal behavior than for example is known to official agencies; this is true across ethnic groups and countries (Jolliffe *et al.*, 2003; Enzmann *et al.*, 2010). A member of the staff at the child's school who knows the child well should be spoken to, to find out if there are behavioral issues in the classroom and in peer relations, and the latest school report should be requested along with formal examination results and psychometric test reports, if available.

History and examination

A thorough clinical evaluation should be made (see Chapter 32). There may be a litany of complaints from the parents and it is important to keep a neutral position and show the child or young person that s/he is also being listened to. The quality of parenting needs to be thoroughly assessed. Asking about what happens during a typical day and at a typical weekend is often revealing. Detailed blow-by-blow descriptions should be obtained of disciplinary encounters, so that a clear picture is built up of antecedent events, how the parents reacted and whether any consequences were applied. An evaluation should be made of how negative the parents are, including whether the child is scapegoated for more of the family's difficulties than appears just, and whether the situation borders on emotional or physical abuse. Coercive cycles and negative reinforcement traps that are maintaining the behavior should be explored. Positive involvement in joint activities such as play or common interests needs to be assessed. The clinician should not shy away from asking parents about their own antisocial activities and criminal records, and use of alcohol and drugs, including during pregnancy.

Seeing young persons on their own is crucial. They may reveal emotional concerns including anxiety and depression, and substance and alcohol use that they have withheld from the parent. Gang involvement and witnessing interparental violence should be enquired about. Are there positive times with their parents? Do they feel closeness, can the child seek comfort from them? In young children, what is the quality of attachment to the parent? Because it is easy to become overwhelmed by the saturation of negative events and behavior, it is especially important to ask young persons what they enjoy doing and what they are good at and their hopes for the future. Are there any positive adults in the child's life? What potential protective factors are operating and how might they be built on? Physical examination (see Chapter 35) should include a check for dysmorphic features including fetal alcohol syndrome.

Investigation

It is important to evaluate the presence of both specific and general learning disabilities in individuals with ODD/CD. Poor school performance can often be attributed to a lazy attitude and failure to complete homework, both of which may be present but may mask an underlying cognitive problem. A quarter or more of children with ODD/CD also have specific reading retardation (defined as having a reading level two standard deviations below that predicted by their IQ) or dyslexia (Trzaskowski *et al.*, 2006; see Chapter 53). While this may in part be due to lack of adequate schooling, there is good evidence that the cognitive deficits often precede the behavioral problems. General learning disability (see Chapter 54) is often missed in children with conduct disorder unless IQ testing is carried out (see Chapter 34). The rate of conduct disorder rises several-fold as IQ gets below 70 (see Chapter 54).

Differential diagnosis and formulation

Differential diagnosis

Making a diagnosis of ODD or CD is usually straightforward but comorbid conditions are often missed. A particular pitfall is to fail to diagnose comorbid ADHD despite symptoms being there, because there is a chaotic or abusive home background or because there have been several recent disruptive moves of a home or school; likewise, a disorganized pattern of attachment does not exclude ODD/CD. The differential diagnosis may include:

1 Attention Deficit Hyperactivity Disorder. Any of the three core symptoms, impulsivity, inattention and motor overactivity can be misconstrued as antisocial, particularly impulsivity, which is also present in ODD/CD and does not of itself indicate ADHD (see Chapter 55). A careful history of ability to attend and be still both at home and school will usually reveal ADHD if present, in conjunction with a school visit or standardized questionnaire from the teacher. In contrast, antisocial behavior is not a feature of pure ADHD (see Chapter 55).

2 Mood Disorders. *Depression* can present with irritability and oppositional symptoms but unlike typical ODD/CD, mood is usually clearly low and there are often vegetative features (see Chapter 63). ODD has angry outbursts as one of its characteristics, but if irritability is marked then *DMD Disorder* should be considered: although disobedience is not a core feature, diagnostic overlap is very marked. Likewise, *Intermittent Explosive Disorder* shares many features with ODD/CD but aggression is not premeditated or committed to achieve a tangible objective, nor are the nonaggressive symptoms such as lying or stealing present. Early *Bipolar Disorder* should not be diagnosed without clear evidence of manic features such as racing thoughts, increased activity or energy and expansive mood (see Chapter 62). Low self-esteem is the norm in ODD/CD, as is a lack of friends or constructive pastimes. Therefore it is easy to overlook more pronounced depressive symptoms.

3 Adjustment Reaction. This can be diagnosed when onset occurs soon after exposure to an identifiable psychosocial stressor such as divorce, bereavement, trauma, abuse, or adoption. The onset should be within 1 month for ICD-10, and 3 months for DSM-5, and symptoms should not persist for more than 6 months after the cessation of the stress or its sequelae (see Chapter 26).

4 Autistic Spectrum Disorders (ASD). These are often accompanied by marked tantrums or destructiveness, which may be the reason for seeking a referral. As with ODD/CD, a lack of friendships may also be evident. Enquiring about other symptoms of autistic spectrum disorders (ASDs) should reveal their presence. In particular, unlike children with ODD/CD who have callous-unemotional traits, children with ASD fail to understand social situations and judge accurately the emotions of others. Some children with ODD/CD nonetheless appear to have some autistic features, in which case more detailed evaluation is indicated (see Chapter 51).

5 Antisocial/Dyssocial Personality Disorder (ASPD). In DSM-5 ASPD cannot be diagnosed under 18, although it requires evidence of conduct disorder before the age of 15 years. ICD-10 does not mention a lower age limit, but the criteria do not appear in the section on childhood disorders and clinicians are usually reluctant to apply the diagnosis outside adulthood (see Chapter 67). Nonetheless, it is becoming apparent that callous-unemotional traits can be reliably identified in middle childhood, have substantial continuity and a significant genetic contribution to their causation (see Chapter 68), so it is worth recognizing their presence.

6 Subcultural Deviance. Some youths are antisocial and commit crimes but are not particularly aggressive or defiant. They are well adjusted within a deviant peer culture that approves of recreational drug use, shoplifting and so on. Drug and alcohol usage should always be asked about, but often this will fall short of a diagnosable dependence syndrome, both in terms of symptoms and major impairment.

Multiaxial system

ICD-10 has a scheme for multiaxial assessment for children and adolescents. *Axis One* refers to clinical syndromes; *Axis Two* refers to specific learning disabilities and *Axis Three* to general learning disabilities; *Axis Four* to medical conditions, *Axis Five* psychosocial and environmental problems, and *Axis Six* to the global level of functioning which can be measured for example using the Children's Global Assessment System (CGAS; Shaffer, *et al.*, 1983). While DSM-IV had a fairly similar system, it has been abandoned in DSM-5 as it was not widely used in adult practise. In many ways this is a loss, as a multiaxial approach forces the clinician to consider wider factors beyond the presenting symptomatology.

Formulation

The formulation should synthesize all that has been learned from the assessment about the child's predisposing, precipitating, perpetuating, and protective factors in an individualized narrative way, rather than simply impersonally applying a diagnosis. The first assessment session is crucial for engaging the family and identifying strengths that can be worked with, to bring about therapeutic change.

Intervention

The next sections will cover treatment of children aged 2–12. For prevention, please see Chapter 17. For treatment of delinquent teenagers, including Functional Family Therapy and Multisystemic Therapy, see Chapter 49.

Principles

Personalizing the treatment plan

The treatment plan should follow the assessment and fit the particular needs of the child and family. Many risk factors have been delineated in this chapter, but usually not all occur in the same child, who typically will be functioning differently according to context, with for example, a different pattern exhibited at home compared with the school. Intervention needs to be tailored according to the needs and strengths of the family, and be reasonably congruent with their beliefs, otherwise disengagement is particularly likely in this patient group whose lives are often not well organized and who are often suspicious of authority figures such as health professionals.

Engaging the family

Any family coming to a mental health service is likely to have some fears about being judged as bad and possibly mad. Dropout rates in treatment for conduct problem families are high—often up to 60% (Kazdin, 1996). Practical measures, such as assisting with transportation, providing childcare, and holding sessions in the evening or at other times to suit the family are all likely to facilitate retention. Forming a good alliance with the family

is especially important. Once engaged, the quality of the therapist's alliance with the family affects treatment success, accounting for 15% of the variance in outcome in the meta-analysis by Shirk and Carver (2003). Making a strong alliance is not just a characteristic of the therapist, but more compliant families make it easier to plan constructive treatment jointly (Green, 2006).

Choosing which treatment modality to use

The behavior may predominantly occur in the home, at school, with peers, or in the community; or it may be pervasive. Interventions need to address each context specifically, rather than assuming that successful treatment in one area will generalize to another. Thus improvements in the home arising from a successful parent training program will not usually lead to less antisocial behavior at school—the meta-analysis by the National Institute for Health and Care Excellence, NICE (2013) found that despite a moderate-to-large effect-size (0.6 sd) at home, there was no carry-over at all to school. Therefore for cases with difficulties that are mainly at home, parent training could be the first line of treatment. If classroom behavior is a problem and a school visit shows that the teacher is not using effective methods, then advice to the teacher and other school staff can be very effective (see below). Where there are pervasive problems including fights with peers, then individual work on anger management and social skills should be added; on its own, anger management is unlikely to be as successful as when it is combined with other approaches. For most cases, medication is controversial and generally best avoided; possible indications are discussed below.

Encouraging strengths

Identifying strengths of the young person and the family is crucial. This helps engagement, and increases the chances of effective treatment. Encouragement of abilities helps the child spend more time behaving constructively rather than destructively—for example, more time spent playing football is less time spent hanging round the streets looking for trouble. Encouragement of prosocial activities—for example, to complete a good drawing, or to play a musical instrument well—also increases achievements and self-esteem and hope for the future.

Treating comorbid conditions

In clinical referrals, comorbidity is the rule rather than the exception. As noted above, common accompaniments are depression and ADHD; a number will have posttraumatic stress disorder (PTSD). In recent years there has been increasing recognition of the overlap with autistic spectrum disorders, where so-called challenging behavior often amounts to ODD (see Chapter 51), and that a minority will have psychopathic traits (see Chapter 68). Each of these conditions requires appropriate management in its own right.

Promoting social and learning skills

Treatment involves more than the reduction of antisocial behavior—thus for example, stopping tantrums and aggressive outbursts, while helpful, will not lead to good functioning if the child lacks the skills to make friends or to negotiate: positive behaviors need to be taught too. Specific learning disabilities such as reading retardation/dyslexia, which is particularly common in these children, need treatment, as do more general difficulties such as planning homework.

Following guidelines

A number of authoritative professional bodies have produced guidelines for the assessment and treatment of ODD/CD. The American Academy of Child and Adolescent Psychiatry published practise parameters for the assessment and treatment of Conduct Disorder in 1997 which are now a little dated, but the guidelines for ODD were published in 2007 so are reasonably up-to-date. The US Center for Education and Research on Mental Health Therapeutics (CERT) produced a guideline on “Maladaptive aggression in youth,” covering engagement as well as treatment (Rosato *et al.*, 2012) and the UK NICE recently published a full guideline on antisocial behavior and conduct disorders covering assessment, treatment, and cost-effectiveness (NICE, 2013). The assessment and treatment approaches advocated here are consistent with each of these guidelines.

Treating the child in a natural environment

Most of the interventions described below are intended for outpatient or community settings. Psychiatric hospitalisation is very rarely necessary; there is no evidence that in-patient admissions lead to gains that are maintained after the child is returned to the family. The objective of treatment is to enable the child to cope with the environment he or she lives in usually, and alter the environment where it is harmful. Where there is parenting breakdown or total inability to manage the child, then foster care may be necessary. Not all cases of conduct disorder need to be seen in child and adolescent mental health services, and indeed with the prevalence of 5% that would be impossible; less complicated cases may be seen, for example for parent training given by local voluntary organizations, so long as staff are adequately trained and there is a clear onward pathway if this is ineffective.

Family interventions

Even where the antisocial behavior appears to have arisen “in a clear blue sky” without adverse family risk factors, living with a child with marked antisocial behavior can itself lead to coercive parenting styles, which in turn may exacerbate the problems. Therefore improving family risk factors such as coercive parenting is likely to be beneficial, whether or not they were originally implicated as a cause.

Parent training

Parent training programs are the mainstay of treatment of ODD/CD, especially with younger children below the age of about eight. They are designed to improve parents’ behavior management skills and the quality of the parent–child relationship. Most parenting programs target skills, such as promoting play and developing a positive parent–child relationship, using praise and rewards to increase desirable social behavior, giving of clear directions and rules, using consistent and calm consequences for unwanted behavior, and reorganizing the child’s day to prevent problems. Some parenting programs also have add-on elements to address parental problems that interfere with their ability to learn how to parent better, such as parental drug/alcohol abuse, maternal depression and violence between parents. Treatment can be delivered in individual parent–child appointments, or in a parenting group. Individual approaches offer the advantages of “*in vivo*” observation of the parent–child dyad and therapist coaching and feedback regarding progress; groups are more cost-effective and enable parents to learn from each other. Parenting programs are discussed in detail in Chapter 37.

Two examples of model programs for individual work with parents that are empirically supported include *Helping the Noncompliant Child* (McMahon *et al.*, 2010) and *Parent Child Interaction Therapy* (Zisser & Eyberg, 2010). Group treatment has been shown to be equally effective, and offers opportunities for parents to share their experience with others who are struggling with a disruptive child. Group treatments emphasise discussion among group leaders and parents, and may use videotaped vignettes of parent–child interactions that illustrate the “right” and “wrong” ways to handle situations. Two well-known group treatments are the *Incredible Years Program* (Webster-Stratton and Reid, 2010) and the *Positive Parenting Program* (Triple P; Sanders, 2012), both of which have been disseminated throughout many countries in the world and translated into many languages (see Chapter 37).

Parent training is the most extensively studied treatment for conduct problems, and the meta-analysis in 2013 by NICE found a mean effect-size of 0.54 sd as rated by parents; this was not just a rater effect, as clinician/researcher ratings had an effect size of 0.69, and direct observation 0.40. This is in contrast to parent training for ADHD, where despite parental ratings suggesting effectiveness, independent ratings suggest little effect (Sonuga-Barke *et al.*, 2013).

Recently, some programs have included an element of training parents to read with their children in addition to behavior management, with the idea of targeting multiple risk factors for antisocial behavior. Scott *et al.* (2010a) combined a 12-week behavior management program with a relatively intense, detailed reading program (10 2-hour sessions) for 5- and 6-year-olds. In an RCT, this combination reduced the rate of oppositional defiant disorder by half and increased reading age by 6 months; ADHD symptoms in semistructured interview were also reduced. This kind of approach is promising since it

is relatively inexpensive, using parents as the only vehicle for treatment, yet hits multiple risk factors for poor outcomes in antisocial behavior (parenting, oppositional defiant disorder, ADHD symptoms, reading ability). A subsequent trial showed a similar package worked equally well for parents from ethnic minorities (Scott *et al.*, 2010b). However, as for most therapies, parent training does not work for all cases and there are few trials of what to do when it has failed. Moving from group to intensive individual work has been advocated, and Scott and Dadds (2009) provide a framework for tackling this in a systematic way by drawing upon attachment theory, family systems, and motivational interviewing. Approaches such as these now need empirical testing, as do booster trials to prevent relapses.

Family systemic therapies

Typically, family systemic therapies involve all family members attending. Their goals differ according to the style and underlying theory of the particular variant of therapy. For example, structural family therapy as pioneered by leaders such as Minuchin (1974) would try to restore clear boundaries of authority of the parents over the child, since often antisocial children have become domineering in their own homes. Other forms of family therapy try to improve patterns of communication that have gone wrong, and “systemic” variants try to reveal and address relevant factors that impinge on the family system from both within and outside the family. There have been few if any good quality evaluations of family or systemic therapies for childhood antisocial behavior (see Chapter 39). In contrast, in adolescents there have been several trials of particular brands of systemic family therapy such as Functional Family Therapy and Multisystemic Therapy which have often proved successful with a notably difficult client group (see Chapter 49).

Child therapies

Cognitive-behavioral therapies and social skills therapies for ODD/CD typically aim to (i) reduce children’s aggressive behavior such as shouting, pushing and arguing; (ii) increase prosocial interactions such as entering a group, starting a conversation, participating in group activities, sharing, cooperating, asking questions politely, listening, and negotiating; (iii) correct the cognitive deficiencies, distortions and inaccurate self-evaluation and (iv) ameliorate emotional regulation and self-control problems so as to reduce emotional lability, impulsivity, and explosiveness, enabling the child to be more reflective and able to consider how best to respond in provoking situations (Larson & Lochman, 2011). While child CBT therapies were originally mainly used with school-age children and older, more recently they have been successfully adapted for preschoolers (Webster-Stratton & Reid, 2010; see Chapter 38).

An example is Lochman’s *Coping Power Program* (Larson & Lochman, 2011). This is fairly lengthy, comprising 33 1-hour group sessions, with monthly individual meetings. Training focuses on interpretation of social cues, generating prosocial solutions to problems, and anger management with arousal

reduction strategies. Treatment is delivered in groups of 5–7 children by two therapists. Sessions include imagined scenarios, therapist modeling, role plays with corrective feedback and assignments to practise outside of sessions. Parent and teacher training components have been developed as adjunctive treatments. Evaluations demonstrate reductions in aggression and substance use, and improved social competence (Lochman *et al.*, 2012). Independent replications are now needed.

The literature is generally not supportive of the effectiveness of individual, psychodynamic psychotherapies, art and drama therapies in this population, especially when used as a sole treatment modality, although decisive studies are yet to be undertaken (Fonagy & Target, 2008).

Interventions in school

This section is a brief summary of interventions for children with established antisocial behavior. Preventive programs including those promoting social and emotional learning are covered in Chapter 17. Typically, teachers are taught techniques that they can apply to all children in their class, as well as to those exhibiting the most antisocial behavior. Successful approaches use proactive strategies and include a focus on positive behavior and group interventions, and combine effective instructional strategies with effective behavioral management. Typically, they target four areas of functioning. First, they promote positive behaviors such as compliance and following established classroom rules and procedures. Second, the interventions prevent problem behaviors such as talking at inappropriate times and fighting. Third, they teach social and emotional skills such as conflict resolution and problem solving. Fourth, they prevent the escalation of angry, acting out behavior.

To date there have been relatively few controlled trials of such interventions; the meta-analysis by NICE (2013) found eight trials of good quality in all, the mean teacher-rated effect size was 0.43 sd but researcher-rated and independent observer-rated effects were not significant. Therefore there is the possibility that improvements that teachers see are purely due to rating bias. However, the individual trials that did show significant effects by independent observers were the ones that used a program with more training and fidelity in adherence to the manual (e.g., Forster *et al.*, 2012); they include those done in low and middle income countries (Baker-Henningham *et al.*, 2012), where such interventions can be combined with parenting programs (see Chapter 37). This is a promising domain worthy of further research.

In recent years in some countries such as the UK and the USA there has been a surge in the use of teaching assistants in classrooms. Often these staff are not well paid or given much training, yet in some schools there will be perhaps two teaching assistants for every teacher in a classroom of say 30 pupils. A systematic review (Alborz *et al.*, 2009) concluded that there was insufficient evidence to show effectiveness for disruptive pupils in class, but that practise varied widely, thus for example some assistants sat close to the child to encourage prosocial behavior and prevent

disruptive behavior, while others sat at the back of the class to try to promote the child's independence. Given the considerable resource expenditure on this intervention, further research is indicated.

Medication

There are differing views as to the usefulness of medication in ODD/CD. Prescriptions of medications, particularly antipsychotics such as risperidone, are increasing considerably, especially in the USA. In the UK general use of medication would not generally be supported as good practise because well-replicated trials of effectiveness are limited, particularly for children without ADHD, and there is a significant risk of unwanted side-effects.

The best-studied pharmacological interventions for youth with ODD/CD are psychostimulants (methylphenidate and dexamfetamine), when used with children with comorbid ADHD. In these circumstances, there is good evidence that reduction in hyperactivity/impulsivity will also result in reduced conduct problems (see Chapter 55). There is insufficient reliable evidence to decide whether stimulants reduce aggression in the absence of ADHD; one study by Klein *et al.* (1997) found that improvements in CD symptoms were independent of ADHD symptom reduction, whereas Taylor *et al.* (1987) did not.

Other pharmacological approaches for antisocial behavior have tended to target reactive aggression and over arousal, primarily in highly aggressive and psychiatrically hospitalized youth. Medications used in these conditions include antipsychotics, those purported to target affect dysregulation (e.g., buspirone, clonidine), and mood stabilizers (e.g., lithium, carbamazepine) (Rosato *et al.*, 2012). In the last few years, the use of antipsychotics such as risperidone and aripiprazole in out-patient settings has been increasing. However, there is only modest evidence for their effectiveness in conduct disorder in normal IQ children without ADHD. These newer antipsychotics, while not especially sedating, have substantial side-effects, for example risperidone typically leads to considerable weight gain, and the prevalence of long-term movement disorders in the long-term is unknown (see Chapter 43). The NICE (2013) meta-analysis of antipsychotics for ODD/CD found only three suitable trials, and these were of moderate quality only. The mean effect size as rated by parents was 0.49 sd, but there were no significant effects on researcher/clinician or teacher ratings; no study used independent observation; the majority of the children had comorbid ADHD. In contrast, the meta-analysis by Rosato *et al.* (2012) included studies with children with ADHD, learning disabilities, and autism. It reported an overall effect size of 0.72 over a mean period of 8 weeks treatment, during which the children (average age 9 years) gained 1.8 kg. This review recommends that if antipsychotics do not work, a mood stabilizing medication should be added. Thus this review takes a very different stance on treatment with medication from that taken by NICE, stating that "The evidence on the effect of psychosocial interventions on maladaptive

aggression is limited"; many authors disclosed payments from drug companies.

When might antipsychotics be contemplated? Clinical experience suggests they can lead to the helpful reductions in aggression in some cases, especially where there is poor emotional regulation characterized by prolonged rages. Prescribing antipsychotics for relatively short periods (say up to 4 months) in lower doses (say no more than 1–1.5 mg risperidone per day) where full evidence-based psychosocial interventions with both the family and the child are failing can help families cope; during this time it is crucial to continue to work at effective psychological management.

Conclusions

Children with ODD/CD deserve serious consideration since if untreated the outlook over the lifespan is notably negative for many of them. Fortunately, a great deal has been discovered about what leads to the condition, and crucially, what treatments are likely to work to make it better. However, in many countries there are few services available for them, including in rich countries, where they may be excluded from child and adolescent mental health services unless they have a comorbid conditions such as ADHD. While much further research needs to be done to understand both the causation and how best to treat these children, there are ample opportunities already to improve their plight by deploying greater resources to help them.

Substance-related and addictive disorders

Thomas J. Crowley and Joseph T. Sakai

Department of Psychiatry, University of Colorado School of Medicine, Aurora, CO, USA

Introduction

Substance use disorders (SUDs), being among the most prevalent psychiatric disorders in persons 9 to 21 years old (Copeland *et al.*, 2011), are profoundly important to child and adolescent psychiatry. Considering the United States, each year about 10% of adolescents begin drinking alcohol, 6% start using illicit drugs, and 5% initiate cigarette smoking. Of course, this is only starting drug use, but 7% in that age range have diagnosable SUDs. Rare before age 10, the number of new SUD cases rises rapidly through adolescence, peaking around age 20 and declining thereafter; new cases are unusual after age 25. However, adolescent SUDs often persist into young adulthood, and those persisting further become leading causes of adult deaths.

Although such US data are unusually detailed, they cannot describe adolescents world-wide. For example, a cross-national study (Hibell *et al.*, 2012) in 36 European countries (with comparative US data) asked 16 year-old youths whether they had been drunk in the last 30 days. The percentage answering “yes” in selected countries included: Denmark, 37% (highest); UK, 26; Norway, 14; USA, 14; and Albania, 6 (lowest). Clearly, clinicians treating adolescent SUDs must track their own regional epidemiologic trends.

Adolescent-onset SUDs often co-occur with risk-taking, impulsivity, inattention, and conduct problems in a broad trait of personality and temperament termed “behavioral disinhibition ... a highly heritable general propensity to not constrain behavior in socially acceptable ways, to break social norms and rules, and to take dangerous risks, pursuing rewards excessively despite dangers of adverse consequences” (American Psychiatric Association, 2013; cf., Iacono *et al.*, 2008). Because early intense substance use is dangerously risky and clearly involves “pursuing rewards excessively despite dangers of adverse consequences,” SUDs are a central manifestation of high behavioral disinhibition. Conduct disorder, strongly comorbid with early-onset

SUD, is another such manifestation. For example, nearly 50,000 16-year-old students in some 16 European countries completed self-report assessments of their antisocial behavior, depression, self-esteem, and anomie. Although high scores on each of those measures significantly predicted heavy substance use, the association with antisocial behavior was by far the strongest (Hibell *et al.*, 2009).

Because youths with this trait often do very dangerous behaviors, like driving while drinking, using multiple substances, carrying weapons, or fighting frequently, they are at serious risk for both accidental injury and homicide, which are the most common causes of death in American adolescents. A case example highlights these issues.

Case Report. A 16-year-old Hispanic female was referred to a university day-treatment program for substance-involved adolescents. She met DSM-IV criteria for abuse of cannabis and cocaine; dependence on alcohol, nicotine, and hallucinogens; and major depression. Conduct problems included probation, car thefts, shoplifting, truancy, runaways, curfew violations, driving without a license, lying, and fighting. Both parents had histories of substance problems and court convictions.

The girl first used marijuana at age 8. An excellent student through age 12, her marijuana use then escalated sharply. At age 13 she “hung out with the wrong kids,” and by age 14 she was chronically truant, using drugs at home with gang friends.

Day Treatment included individual and group counseling to diminish drug use and increase prosocial behavior, family treatment to enhance parental control, antidepressant medication, and urine monitoring. She made excellent progress, remained abstinent, spoke and wrote thoughtfully about her past behavior, and was much liked by treatment staff. At discharge after 6 months staff rated her treatment as “successful” and referred her for follow-up care elsewhere.

Two years later newspapers reported that the now eighteen year-old woman and a much older, frequently-arrested man had burglarized a garage. After a high-speed chase police caused the couple’s car to crash. When the man brandished a gun, police shot them both dead. Newspapers reported that both bodies contained

methamphetamine, and that the woman had been arrested five months earlier for manufacturing drugs.

Such complex patients may present multiple drug and conduct problems, other psychiatric disorders, improvement during (and relapse after) treatment, a prolonged relapsing course, familial substance and antisocial problems, pursuit of exciting pleasures while ignoring dangers, and mortal risk. The treatment goal often is to minimize the risk for psychological and physical morbidity and mortality.

Most adolescents in substance treatment have diagnosable SUDs on several substances, often including alcohol, tobacco, cannabis, or other locally prevalent drugs. Treatments for withdrawal syndromes and medications for SUDs usually target specific drugs, while psychosocial treatments typically address drug-taking generally.

It is estimated that 7% of 12–17-year-old Americans needed treatment for an alcohol or illicit-drug SUD in 2011. However, appropriate facilities administered such treatment to only 0.6%. Without enough doctoral-trained clinicians to meet that extreme public-health need, non-doctoral substance-abuse counselors are required. However, these patients' clinical complexity does demand highly trained supervising professionals, including child and adolescent psychiatrists. We present a model addressing that public-health need with non-doctoral counselors conducting most psychosocial treatments, supervised by senior social workers, psychologists, and psychiatrists.

Definitions, comparative nosology

A drug is a natural or synthetic chemical substance that affects living processes. Substance-related disorders are psychiatric disorders developing during or following substance use, and attributable to it. The drugs that most often produce substance-related disorders include tobacco, alcohol, cannabis, stimulants (cocaine, amphetamine, methamphetamine, mephedrone, and others), opioids, sedative-hypnotic and anxiolytic agents, inhalants (volatile hydrocarbons), phencyclidine or other arylcyclohexylamines, and other hallucinogens. Numerous other substances, including nitrous oxide, amyl- or butyl-nitrite, or anabolic steroids also may produce these disorders.

Adolescents experiment with substances. Where is the line between experimentation and diagnosable SUD? Because early initiation of use tends to predict later substance problems, risky substance experimentation warrants early intervention (discussed below), but substance use is not SUD, even in young teens. Nevertheless, some adolescent users do develop SUDs, as described next.

The *Diagnostic and Statistical Manual of Mental Disorders, Edition 5* (DSM-5; American Psychiatric Association, 2013), like the previous DSM-IV, divides substance-related disorders into two categories. SUDs are conditions in which the person continues using a substance despite experiencing serious problems caused by that substance. These disorders include, for

example, alcohol use disorder or cocaine use disorder. Substance *induced* disorders develop as a consequence of prior substance use, and include, most obviously, intoxication and withdrawal. These additional disorders also may be induced by substances: neurocognitive, psychotic, depressive, bipolar, panic, anxiety, sexual, sleep, and obsessive-compulsive disorders, as well as delirium.

DSM-5 uses the same 11 criteria for diagnosing each different SUD (Hasin *et al.*, 2013), and many adolescent patients qualify for more than one of these diagnoses (e.g., both alcohol use disorder and cannabis use disorder). The criteria were adopted from the earlier DSM-IV with the intention that DSM-IV and DSM-5 would diagnose the same groups. However, DSM-IV's criterion, "recurrent substance related legal problems," was replaced because drug laws vary widely in different jurisdictions. "Craving" replaced it and is assessed with, for example, "Do you sometimes feel a strong desire or urge to use [substance]?" The resulting 11 diagnostic criteria fall into four broad problem categories: impaired control, social impairments, risky use, and pharmacologic problems (tolerance, withdrawal). Meeting more criteria does indicate more severe functional impairment and more serious disorder, so SUD severity is estimated by counting the criteria one meets: 0–1, no diagnosis; 2–3, mild SUD; 4–5, moderate; >5, severe.

The 11 diagnostic criteria for SUD include tolerance and withdrawal, but those also occur during medical treatment with, for example, stimulants, opioids, sedative-hypnotics, or anxiolytics. Thus, during appropriate treatment with these medications DSM-5 does not permit a SUD diagnosis unless the person meets criteria beyond tolerance and withdrawal.

Cannabis produces a withdrawal syndrome somewhat similar to nicotine's. DSM-5, unlike previous editions, recognizes cannabis withdrawal as a substance *induced* disorder.

The *International Classification of Diseases* (ICD) of the World Health Organization (WHO) classifies and provides numeric codes for physical and behavioral disorders (WHO, 2010). WHO's current, 10th revision (ICD-10) will be replaced by ICD-11 in 2015. Nations modify and adopt the ICD on their own schedules. For example, the USA will use ICD-9 in a modified version (ICD-9-CM, Clinical Modification) until it adopts ICD-10 in 2014.

Many of DSM-5's 11 diagnostic criteria for SUD are implied in ICD's "Dependence Syndrome": "A cluster of behavioral, cognitive, and physiological phenomena that develop after repeated substance use and that typically include a strong desire to take the drug, difficulties in controlling its use, persisting in its use despite harmful consequences, a higher priority given to drug use than to other activities and obligations, increased tolerance, and sometimes a physical withdrawal state." However, ICD's "Harmful Use" ("A pattern of psychoactive substance use that is causing damage to health ...") is not in DSM-5.

Saunders (2006) concluded that DSM-IV's substance dependence disorder and ICD's Dependence Syndrome were similar in structure and functioned well; DSM-IV's substance abuse

diagnosis performed moderately well; and ICD's Harmful Use performed poorly. Hasin *et al.* (2013) expect that DSM-5, maintaining most of DSM-IV's abuse and dependence criteria while adding ICD's "craving," will identify persons with mild to severe substance problems.

ICD provides diagnoses comparable to several of DSM-5's substance *induced* disorders. However, DSM-5 does not recognize ICD's "Residual and Late-Onset Psychotic Disorder," understood as a persistent drug-induced psychosis.

Neither DSM-5 nor ICD define "addiction" nor include the term in the name of any specific disorder, perhaps considering it pejorative. Curiously, however, DSM-5's chapter on these disorders is titled "Substance Related Disorders and Other Addictions" (see Non-Substance "Behavioral Addictions," below).

In making differential diagnoses each SUD must be distinguished from: (i) unintentional substance exposure; (ii) intentional substance use not meeting criteria for a SUD; (iii) unrecognized comorbid SUDs (e.g., diazepam and cocaine use disorders together); (iv) substance induced disorders (e.g., intoxication); and (v) other medical disorders. Each substance *induced* disorder must be distinguished from: (i) its cognate disorder (e.g., substance induced mood disorder, vs mood disorder); (ii) other substance induced disorders (e.g., substance induced delirium vs substance induced neurocognitive disorder); and (iii) other medical disorders.

The criteria for diagnosing SUDs are both valid and reliable. However, because SUDs frequently are comorbid with, and concealed by, other conditions, clinicians must actively consider them, accurately diagnose them, and initiate appropriate treatment.

Epidemiology

Prevalence of use

Substances are used worldwide, and substance experimentation is common among children. The substances used vary by age of the individual and availability of the drug; for example, young children may have difficulty accessing cocaine, but inhalants in glues, paints, cleaning agents, or fuels are easily available in many homes. About 1 in 8 American eighth graders (ca. age 13) have used inhalants, but by the mid-teens alcohol, nicotine, and cannabis use predominate, and few use inhalants by late adolescence. Although the legal age for possessing alcohol in the United States is 21 years, in 2011 about 70% of high school seniors (ca. age 17) had used alcohol, and nearly 1 in 4 reported having had at least 5 drinks on one occasion in the last 2 weeks. Although these students perceived high risk from, and disapproval of, cigarettes, about 1 in 6 had smoked in the past month. Patterns of illicit drug use are equally concerning; about half of American high school seniors have used an illicit drug, including 36% using cannabis and 15% misusing prescription medications (especially opioids and amphetamines) in the last year. Fortunately, although many adolescents experiment with substances, most who try them will not progress to a clinical

SUD diagnosis. For example, among U.S. adolescents only about 7% met criteria for a SUD during the past year.

Comparisons of 16-year-old students in some 36 European countries and the USA (Hibell *et al.*, 2012) are partially presented in Table 66.1. The data show considerable country-to-country variability in substance use, although a country's high prevalence of use of one substance does not necessarily predict high use of another substance. Generally, the UK and USA show mid range prevalence figures.

Comorbid disorders

Among American adolescents with SUD, about 60–80% have conduct disorder; 30–50 percent, attention-deficit/hyperactivity disorder; 15–25%, major depressive disorder; and 15–25%, anxiety disorder (Riggs, 2003). Conversely, SUD is prevalent among adolescents utilizing mental health treatment (Kramer *et al.*, 2003); estimates vary, but many with bipolar disorder and psychosis have a co-occurring SUD (Kavanagh *et al.*, 2004; Goldstein & Bukstein, 2010).

Sex differences

Early in development the "default brain" is female, but males' brains are "masculinized" early in development, leading to numerous male-female brain differences. As a result, males in many mammalian species, including humans, show more risky, aggressive behavior than females. For example, American adolescent boys, more than girls, carry guns or other weapons, drive after drinking alcohol, rarely wear seatbelts, and die from accidental or homicidal injuries. Boys commit three-fourths of juvenile violent crimes. They are much more likely to develop serious conduct problems, and they have higher behavioral-disinhibition scores.

It is surprising, then, that rates of illicit drug, alcohol, and tobacco use, and also of SUDs (about 7%), are similar in adolescent male and female Americans. However, as youngsters age into the late teen years, sex differences in SUD prevalence emerge. After age 17 the prevalence of SUD is, as expected, much higher in males (10.8%) than females (5.6%).

Morbidity and mortality

Tobacco is estimated to be a major factor in about 18% of all American deaths, alcohol in about 3%, and illicit drugs in less than 1%. Illicit drugs vary in relative mortality risks for users—higher for some (e.g., opioid overdose deaths) and lower for others (e.g., cannabis). Unfortunately, sometimes even single uses of some drugs are fatal: inhalants' "sudden sniffers' death" or suffocation, and opioids' respiratory depression.

Motor vehicle accidents are the leading cause of death among 16–19-year-old American youths, and among drivers of that age involved in fatal accidents, about 20% had positive blood alcohol tests. In 2011 about 10% of American high school students (aged 16 and older) reported drinking and driving in the last month.

In 2010 underage drinking contributed to nearly 190,000 visits to American hospital emergency departments. Substance use is

Table 66.1 Range of substance use prevalence (percent of 16 Year-Olds), 36 European countries and USA^a.

<i>Alcohol use</i>			
	Ever use	Past-year use	Drunk in the past year

also associated with suicide, violence, and other risky behaviors. For example, early, severe substance problems are associated with early, high-risk sexual behaviors, and with teen pregnancy. Although injection drug use is generally rare among American adolescents, of adolescents treated for early-onset SUD, about 1 in 6 report injecting drugs by young adulthood, thus risking HIV, hepatitis C, and other infectious diseases.

Treatment admissions

About 7% of 12–17 year olds in the USA had a SUD and needed treatment in 2011, but only about 1 in 12 of those adolescents received it, and of those who did not receive treatment, some 95% believed they did not need it. Not surprisingly, then, many adolescents who do receive treatment for SUD are forced into it through criminal-justice or social-service agencies.

About 140,000 11–15-year old English youths reported regular smoking, 360,000 drank alcohol in the last week and 180,000 had used other drugs in the last month. However, in one year only 22,000 persons under age 18 received specialty substance treatment services. Similarly, an estimated 1 million English people (ages 16–65 years) are alcohol dependent, but only 6% of them per year receive treatment (National Institute for Health and Care Excellence (NICE), 2011). Moreover, such specialty care may be much less available in many countries.

Shifts in substances used

Substance use patterns vary across time. For example, as American physicians increased their prescribing of opioids for pain management, adolescents increasingly accessed prescription

opioid drugs for non-medical use. These drugs became the second most common illicit substances used by high school seniors (ca. age 17). During the same period, rates of alcohol use decreased, while cannabis use increased.

The internet provides access to substances that previously had limited availability. For example, nitrous oxide is now easily purchased on the internet, along with cannisters (“crackers”) that release the gas from cartridges (“whippets”), and balloons to hold the gas for inhalation.

Also, new, abusable substances frequently appear. Recently, American stores have sold smokable synthetic cannabinoid agonists, falsely labeled “incense” and “not for human consumption”; 1 in 10 high school seniors (ca. age 17) reported using them in a recent year. A new stimulant drug, methylenedioxypyrovalerone, has been sold as “Bath Salts.” In addition, old drugs find new uses. Dextromethorphan, a non prescription antitussive, in high doses produces hallucinatory episodes called “Robo-tripping” or “using Triple C’s” from the products’ brand names.

Regional and global prevalence variations

World estimates suggest that alcohol contributes to about 2.5 million deaths annually, with about 69 million years of productive life lost; some 230 million people used illicit drugs in 2010, with 15–39 million having problematic drug use (Degenhardt & Hall, 2012). There are substantial geographic variations in drug use prevalence, with higher rates in higher-income countries (although data from lower-income countries often are lacking). More use also occurs in countries that produce or transport

drugs. Regional variations in availability and cultural acceptance of specific drugs also impact use patterns, including age of onset of substance use; by age 13, about 1% of Greeks have tried marijuana or hashish, about 8% of French youths, and about 15% of Americans.

Genetic and environmental risk factors

Familiality

Substance problems cluster within families. In Iceland, where large family genealogies are readily studied, first degree relatives (siblings or parent-and-child) of persons with alcohol use disorder are about twice as likely as others to develop the disorder; the risk decreases in more distant relatives, but remains somewhat elevated even among fifth degree relations. The familiality of illicit drugs is even stronger, and considerable familiality also exists across SUD diagnoses (e.g., an individual with cannabis use disorder having a relative with alcohol use disorder; Tyrfinnsson *et al.*, 2010).

Environmental influences and/or genes may drive such familiality. Twin and adoption studies help to parse heritable and genetic influences, and in childhood and early adolescence risk of substance use is predominantly mediated by environmental factors, especially family environment, but at older ages such environmental effects decrease in importance and genetic effects increase. While many studies have examined initiation of substance use, relatively few have studied the heritability of adolescent SUD. However, the available studies indicate that at least half of the variance is related to genetic effects (Rhee *et al.*, 2003). Thus, whether a child or adolescent tries a substance is influenced strongly by environmental factors (e.g., drug availability, or family attitudes toward drug use), but substance problems in adolescence are more strongly influenced by genetic effects.

Environmental context

The environment in which a child is raised influences risk for SUD outcomes. Many parents who misuse substances model general acceptance of substance use and specific substance use behaviors, allow easy substance access, offer little support for prosocial behaviors, share drugs with their children, and provide limited supervision. Affectively hostile and inconsistent parenting, paired with a strong-willed child who has poor self control, may lead to high parent-child conflict, reduced parental engagement, and poorer monitoring. Having a same-sex drug-misusing sibling, older but close-in-age, increases the risk of drug misuse (Kendler *et al.*, 2013). Neighborhood, school, peers, and important extra-familial adults further influence drug availability and acceptability, and families influence those factors by encouraging or discouraging specific extracurricular activities and by choosing the child's school and neighborhood of residence.

Genetic risk

Although specific environmental risks for later SUD are relatively well defined, information on specific-substance risk genes (e.g., just alcohol, or just cocaine) is weak. An exception in many East Asians is genetic variants in aldehyde dehydrogenase genes that produce a disulfiram-like impact during alcohol metabolism; resulting reductions in alcohol use disorder comprise an effect large enough to be of public health importance. Also, certain GABRA2 genotypes are associated with alcohol use disorder. Variants in nicotinic receptor genes have been associated with nicotine dependence (Saccone *et al.*, 2007). However, many individuals with SUD use multiple substances, and then a history often shows family problems not with one substance, but with many. Thus, although there probably are many substance-specific genetic factors, this risk for SUD generally appears to be more important.

Genes and environment: joint effects

Numerous twin studies concur that genes contribute about half of the risk for developing any particular SUD, with environment contributing the other half. However, the two contributors are not independent. For example, in gene-environment *correlations*, children in families with high genetic loading for SUD may inherit genetic variants that increase risk for SUD. Their parents, bearing the same genes, also may have SUDs, thus establishing risk-increasing environments around the children. In addition, genetic and environmental factors may *interact* to determine SUD risk; low-risk environments can mute a high genetic risk. For example, helping families out of poverty reduces risk for both antisocial behavior problems and SUD (Costello *et al.*, 2010). Such gene-environment correlations and interactions underscore the complex interplay of genetic and environmental risks for SUD.

Genetic studies of complex traits

Although genes clearly and strongly contribute to SUDs, few specific molecular contributors are known. Molecular studies in complex traits such as SUD suggest that many DNA sites contribute, each adding a very small increase in risk. Together they account for about half of the difference in SUD risk among individuals, but individually each accounts for very little. In addition, earlier studies focused on genes coding for protein products and ignored inter-gene "junk DNA." However, recent work finds that these non coding regions actually contain important gene regulators. Finding these many small genetic contributors will require much more research (see Chapter 24).

Brain function and drug risk-taking

Risk-taking is adaptive in adolescents, who must gradually detach from family, bond and compete with age-mates, practice romantic and sexual behaviors, and move toward adult roles as parent and worker. But concurrently, many also begin taking risks with dangerous drugs. Two psychological traits contribute to that behavioral disinhibition and risk-taking. *Impulsivity* is

a deficiency in self-control and response inhibition, leading to hasty, unplanned behavior, and *sensation seeking* is a disposition to seek out novel, stimulating experiences.

Adolescents' brain structure and function (cf., see Chapter 11) mediate that interrelated behavioral disinhibition, impulsivity, and sensation seeking. First, in adulthood, the dorsolateral prefrontal cortex will exert mature cognitive control over decision-making, often inhibiting risky behaviors; however, those inhibitory influences are weaker in adolescents because their still-maturing forebrains have incomplete cortical thinning and fiber myelination (Giedd *et al.*, 2010). Meanwhile, adolescents' rapidly maturing brain reward system facilitates enhanced reward seeking. Together, matured reward-supporting structures and still-immature inhibitory structures generate risk-taking behavior, including drug risk-taking.

But why do some adolescents, and not others, take really serious drug risks? The ventral striatum (nucleus accumbens), a principal target of dopaminergic neurons, activates vigorously when rewards are expected (Schneider *et al.*, 2012). Among adolescents with essentially no drug exposure, risk-taking and the strength of striatal activation during reward anticipation are strongly, negatively associated (more activation, less risk-taking), and that relationship is even stronger in adolescents who already have started using drugs. Moreover, risk-taking also negatively correlates with gray matter density in the ventral striatum (Schneider *et al.*, 2012). So differences in striatal structure and function are neural markers for individual differences in risk-taking, including drug risk-taking.

In addition, when attempting to inhibit a behavior some youngsters have diminished neural activation in numerous brain regions, and such neural hypoactivation predicts drug and conduct problems several years later (Norman *et al.*, 2011). Apparently, in such adolescents brain mechanisms for inhibiting behaviors malfunction before drug use begins.

So some adolescents' brains are more disposed than others' toward risky drug and conduct problems. Then, drug use itself pharmacologically alters the brain in three steps that promote continued drug-taking (Koob & Volkow, 2010). First, in a *binge-intoxication stage* each dose of an addicting drug acutely reduces firing thresholds (increases firing) in those dopaminergic pathways sometimes called the brain reward system, mediating a subjective "high" that encourages further drug use.

Second, continued use gradually produces a *withdrawal/negative-affect stage*, depleting dopamine and other neurotransmitters, with each successive dose yielding less hedonia and greater post-dose dysphoria (Figure 66.1). Then, terminating prolonged drug use diminishes dopaminergic and serotonergic neurotransmission, activates a corticotropin-releasing-factor stress system, and generates anxiety. Both dopamine release and dopamine D₂ receptor expression decline, reducing sensitivity to rewards. By these means, drugs pharmacologically bias the brain's decision-making machinery toward repeated decisions to obtain and use the drugs, which no longer produce hedonia but mainly function to stop aversive dysphoria. Despite such

Figure 66.1 Schematic illustration of dysphoria induced by repeated intoxication-withdrawal cycles (cf., Koob & Volkow, 2010). Each intoxication leads to a subjective "high", with enhanced response to reward in dopaminergic structures. Each acute withdrawal event results in subjective dysphoria with reduced response to reward. Frequent cycle repetitions gradually suppress subjective "highs", deepening dysphoria. Increasingly, the drug is used to escape dysphoria and achieve normal mood. During abstinence, mood slowly recovers. Source: Reproduced by permission from Crowley *et al.* (2010).

biasing, users still can choose to abstain, but that choice now requires increasingly strong environmental rewards and punishments. Drug-taking becomes more automatic and habitual, and, like other habitual behaviors, its control gradually shifts from the ventral striatum to the dorsal striatum.

Third, after chronic drug use a stage of *preoccupation/anticipation (craving)* persists during periods of abstinence. Relapses then are common, and both animal studies and clinical experience show three types of relapse-provoking stimuli: a dose of the drug, cues associated with the drug (e.g., one's former dealer), or stress.

Finally, many misused drugs damage brain tissue. A general discussion of neurotoxicity is beyond the scope of this chapter, but two drugs do deserve mention. *Inhalants* are the most widely used drugs among 12–13-year-old Americans, and in some countries groups of homeless "street children" have reported prevalence rates as high as 70%. Most American users voluntarily discontinue inhalants later in adolescence, but among those who progress to inhalant use disorder, characteristic white-matter lesions (leukoencephalopathy) develop, producing cognitive impairments.

Neurotoxicity from *methamphetamine* damages dopamine neuron terminals, causing dopamine cell loss, reductions in dopamine transporter and D₂/D₃ receptor availability, diffuse loss of serotonergic terminals, and reduced white matter integrity. Fortunately, better international control of methamphetamine's chemical precursors have sharply reduced its use.

In summary, behavioral disinhibition is an important antecedent risk factor for SUDs. Youths vary considerably in the severity of their behavioral disinhibition, and in three separate

adolescent-twin studies the heritability of that severity exceeded 0.8 (see Chapter 24; Young *et al.*, 2000; Krueger *et al.*, 2002; Hicks *et al.*, 2004). The influence of those genes presumably is expressed in the brain mechanisms described above. Fortunately, this shows that both genes and environment are important; not everyone with severe behavioral disinhibition develops SUDs, and the disorders remit in some who do develop them. Behavioral disinhibition does involve a persisting disposition to make risky choices with drugs and in other domains, but environmental influences from therapists, family members, teachers, judges, probation officers, or governments can steer those choices in less harmful directions. For example, when governments strictly controlled methamphetamine's chemical precursors, they obviously did not reduce some adolescents' persisting disposition to make dangerous decisions, but they did protect many of those youths from being snared by that toxic drug.

Longitudinal course

Factors influencing the course of drug involvement in adolescence and later include, first, a *pharmacologically rewarding drug*. SUDs occur because of pharmacologic interactions between certain chemical substances and brain tissue. As noted above, drugs that do produce SUDs all activate brain dopamine systems, initially inducing hedonic pleasure and biasing the brain's decision-making structures toward continued drug-taking.

Second, *the drug must be available and its use must be accepted* in at least some segments of the user's society. Annual per capita absolute alcohol consumption by persons more than 14 years old is about 17 times greater in European countries, compared to mostly-Muslim Eastern Mediterranean countries, reflecting the striking influence of Muslim restrictions on the social acceptance and availability of alcohol. Correspondingly, Europe's prevalence of alcohol use disorders is about nine times greater than that of those Muslim countries, strongly suggesting that social limits on substances' availability and acceptance also influence the prevalence of SUDs. For that reason many clinicians and researchers are concerned with policies that increase the availability and acceptance of pharmacologically reinforcing drugs, as now is occurring with cannabis in some American states.

Third, *a heritable disposition toward risk-taking* increases one's probability of developing a SUD. Different individuals' severity of behavioral disinhibition can be estimated from their symptom counts for conduct disorder, antisocial personality disorder, SUD, and from measures of hyperactivity, impulsivity, inattention, and novelty-seeking (Young *et al.*, 2000). Among both male and female adolescents a few individuals achieve very high behavioral disinhibition scores, placing them at high risk for early-onset SUD and conduct disorder, often with associated hyperactivity and impulsivity. Among persons with severe behavioral disinhibition the course may include

low self-control as early as 3–5 years of age, with prepubertal impulsive aggression, hyperactivity, lack of persistence, and inattention (Moffitt *et al.*, 2011). Even before any drug use there are P300 (Iacono *et al.*, 2008) and fMRI (Norman *et al.*, 2011) brain abnormalities that predict adolescent SUD and conduct problems. In adulthood many show criminality and continuing substance problems (Fergusson *et al.*, 2009; Moffitt *et al.*, 2011).

Fourth, *age is a critical determinant of SUD risk*. The prevalence of DSM-IV alcohol or illicit-drug SUD among Americans was estimated to be less than one percent at age 12 years, 12% at 16 years, 17% at 18 years, and 24% at age 21. Prevalence then declines to 13% early in the fourth decade, and 3% early in the seventh. Regular substance use by minors requires an available drug, money to purchase it, and periods of limited parental supervision, factors rarely present for young children. However, during adolescence, time spent outside the home with peers increases, along with access to substances. Thus, substance problems are rare before, but common during, adolescence and early adulthood. Those youths who start drug use earliest have the greatest risk for developing SUDs (Dawson *et al.*, 2008), perhaps because more severe behavioral disinhibition and conduct problems characterize those earlier starters. Because SUD prevalence peaks around age 21 and then declines as young adults assume the responsibilities of work and family, many persons, especially males, experience serious substance problems in their late teens and early 20s, with subsequent desistance. However, those with early-adolescent onset of both SUD and conduct problems appear much more likely to have SUDs persisting for many years.

Fifth, as noted above, *environment contributes about half to the risk for developing SUDs*; genes contribute the other half. Many parents with substance and antisocial problems create around their children toxic environments, leading to the gene-environment correlations and interactions previously described.

Sixth, *a balance of rewards and punishments influence the course of SUDs*. In addition to the pharmacologic reward discussed above, social rewards also may maintain drug use. Drug users earn social acceptance from other users. Dealing drugs may get more money than other adolescents have, and sharing drugs may win sexual favors. Such rewards come more quickly than larger rewards for studying in school, and drug-involved persons tend to favor smaller rewards that come sooner over larger ones that come later, a process called "delay discounting." On the other hand, social punishments may suppress drug use, but only if they are significant to the adolescent and seem likely to occur soon after the drug use. When an underage adolescent pays a homeless person to buy alcohol for the adolescent, the probability of detection and swift legal punishment is so low that laws provide little deterrence. On the other hand, a juvenile drug court may successfully motivate abstinence and participation in treatment by requiring frequent court appearances and promptly imposing brief periods of detention for any non-participation in treatment or drug-containing urine samples.

Prevention

Prevention programs generally seek to enhance protective factors (e.g., improving parental monitoring or adolescent self-control) and to reduce risk factors (e.g., aggressive behavior, poor academic performance, or contact with substance-using peers). Programs may be “universal” (delivered to, e.g., all students in one grade at a school), or “selective” (delivered to, e.g., children of alcoholics), or “indicated” (delivered to those already engaging in high-risk behaviors or showing early warning signs). Programs also are classified by the targeted setting or group, such as school-, family-, or community-based (see Chapter 17).

Cochrane reviews of prevention programs for alcohol misuse, tobacco smoking, and illicit drug use are limited by a vast heterogeneity of target populations and components delivered. Many prevention programs lack randomized controlled trials, and considered together the empirical evidence for school-based interventions has been considered “rather weak” (Faggiano *et al.*, 2007). Therefore, most Cochrane reviews provide generic information, such as the number of positive and negative trials, rather than effect-size estimates for similar groups of prevention programs.

Family-based interventions

These interventions often aim to improve parents’ nurturing behaviors toward their children, establish clear boundaries and rules, improve monitoring and supervision, provide reasonable and consistent consequences to rule violations, and reward good behavior. Programs may work to improve children’s social and life skills and often include family practice sessions to improve communication. Enrollment and retention of participants, one potential barrier to progress in family-based interventions, may be enhanced by endorsement from community leaders, convenience of delivery location, use of incentives, and providing meals, transportation, or child care. One example is the Strengthening Families Program, developed in the USA and now used in many countries (Kumpfer *et al.*, 2008). The original program offered 14 2-hour group-based sessions focused on family, parent, and child skill training to prevent drug use and misuse in high-risk offspring; shorter versions have been developed for other groups, and versions also are available for various ages.

School-based programs

School-based programs efficiently target large groups of youths. These curricula may include skill building for social competency, communication, refusal skills, or identifying and avoiding high risk situations, as well as education about drug related risks and harms, or challenging beliefs that overestimate the prevalence of substance use. The Cochrane review of universal school-based prevention programs for alcohol misuse specifically cites three with evidence for effectiveness (see Chapter 42).

The Life Skills Training program utilizes a cognitive-behavioral skills framework. It aims to improve self esteem, communication skills, assertion of one’s rights, building of positive relationships, management of anxiety, problem solving, and resistance to adverse social (including media) influences. The program teaches drug resistance skills and provides education about negative consequences from drugs and alcohol. It addresses the actual prevalence of use. Delivered in the seventh grade (ca. age 12), with booster sessions in both eighth and ninth grades, the program significantly reduces drug-use prevalence in the 12th grade (ca. age 17) (Botvin *et al.*, 1995).

The Unplugged program focuses on improving social and personal skills, such as assertiveness, goal setting, refusal skills, and decision making, while providing education about prevalence of drug and alcohol use (Faggiano *et al.*, 2007). Trained teachers deliver the core program in 12 1-hour weekly sessions, sometimes with additional activities involving peers or parents, to 12–14 year-old students. Eighteen-month follow up demonstrates reduced alcohol and cannabis use (Faggiano *et al.*, 2010).

The Good Behavior Game, a universal school-based prevention program, divides students into competing teams. Each student’s target behaviors (e.g., disruptiveness, aggression) affect team scores, and teams receive rewards, based on their scores. This approach, often employed in early elementary school, does reduce aggressive and disruptive behaviors. In one longitudinal study its effects continued to reduce SUD among young-adult males (but not females), especially those with persistently high aggressive and disruptive behaviors (Kellam *et al.*, 2012). However, the program’s effects appear to dissipate without ongoing teacher training, mentoring, and monitoring (Kellam *et al.*, 2012).

Other programs

Drug education alone has not been found to reduce drug-use behaviors or intentions, but many drug-use prevention programs still mainly provide education about drugs and drug abuse. For example, the Drug Abuse Resistance Education (DARE) program demonstrably has little effect on drug use, but remains widely used in American schools.

Other examples of research-based drug abuse prevention programs are too numerous to review here, but may be found at NIDA (2003), the National Registry of Effective Prevention Programs (2013) (<http://www.nrepp.samhsa.gov/>), and the Centers for Disease Control and Prevention’s Guide to Community Preventive Services (available only at www.thecommunityguide.org).

Limits of prevention research

Several concerns about prevention research for drug and alcohol use have been raised, including potential for publication bias, selecting outcome variables post-hoc, reporting of statistical significance without considering practical significance, reliance on self-reports rather than objective testing of substance use outcomes, concerns regarding the handling of sample attrition

and selection bias, and use of one-tailed statistical tests (Holder, 2010). Conflicts of interest and dual roles also raise concerns; program developers, who often serve as program evaluators, may experience financial gain if a program is successful. The Life Skills Training and Unplugged programs have not escaped such criticism.

Policy

Policies such as alcohol taxation, setting or increasing a minimum age for purchase and use, lowering of allowable blood alcohol concentrations for driving, visible enforcement of drinking and driving laws, and limiting where and when alcohol can be sold measurably affect substance use and harms. The NICE guidelines on “Alcohol-use disorders: preventing harmful drinking” include recommendations to make alcohol less affordable and reduce exposure to alcohol-related advertising among children and young people; such policies may reduce alcohol-related harms.

Screening, assessment

Chapters 32, 33, and 34 address psychiatric and psychological assessments generally. This chapter addresses specific issues of screening and assessing for substance problems.

Screening

Physicians and counselors often screen youths to identify those likely to have substance problems. Screens should be inexpensive, easy to administer and score, and have reasonable sensitivity and specificity. Adolescents may prefer screens completed by computer or paper questionnaire, rather than verbal questioning.

SAMHSA (2013) lists screening instruments (e.g., screening, brief intervention and referral to treatment (SBIRT), AUDIT, AUDIT-C), and SAMHSA (2011) compares many of them. SBIRT (Screening, Brief Intervention, and Referral to Treatment) is discussed in the Treatment Section, below. In another free example, CRAFFT (its name, and a mnemonic for its questions), 2 or more positive responses suggest substance problems:

- C: Have you ever ridden in a *car* driven by someone (including yourself) who was “high” or using alcohol or drugs?
- R: Do you use alcohol or drugs to *relax*, change your mood, feel better about yourself, or fit in?
- A: Do you ever use alcohol or drugs when you are by yourself, *alone*?
- F: Has any *friend*, family member, or other person ever thought you had a problem with alcohol or drugs?
- F: Do you ever *forget* (or regret) things you did while using?
- T: Have you ever gotten into *trouble* while using alcohol or drugs, or done something you would not normally do (break the law, rules, or curfew; engage in behavior risky to you or others)?

Substance screens ask adolescents about illegal behaviors, raising issues about parental consent, youth assent, and confidentiality (cf., SAMHSA, 2011). Since requirements vary in different jurisdictions, a detailed discussion of this is beyond the scope of the chapter.

Assessment

An adolescent’s substance assessment asks many questions to answer ten fundamental ones: (i) Are there serious life problems (e.g., frequent intoxications, intravenous drug use, fighting, carrying weapons, extensive truancy, criminality, unprotected intercourse, unplanned pregnancy, experience of abuse or neglect, depression, or suicidal thoughts or actions)? (ii) Are emergency responses required? (iii) Do substance use and behavioral disinhibition contribute to the problems? (iv) How much of which substances are used, and by what route of administration? (v) Is there a family history of substance and disinhibition problems? (vi) Have parental care, supervision, and monitoring been adequate? (vii) Are the problems exacerbated or reduced by other environmental factors (e.g., other family, friends, school, church, therapists, or juvenile-justice or welfare agencies)? (viii) What may block or facilitate a treatment alliance with the patient and family? (ix) Regarding goals, if treatment works, what could reasonably be improved one year hence? (x) What psychosocial and pharmacologic treatments will be needed to achieve the 1-year goal, and to maintain progress thereafter (cf., see Chapter 32).

Answers to these questions will inform the selection of a treatment venue (outpatient, residential, etc.) and treatment selection and execution. For the public-health reasons cited in this chapter’s Introduction, the chapter focuses on public clinics in which a psychiatrist, psychologist, or senior social worker supervises masters- or bachelor-level counselors who conduct most assessments. In other settings the supervisor may conduct them personally.

First contact

Few substance-using adolescents seek treatment on their own. The first clinic contact usually originates with referring court or welfare workers, or the adolescent’s family. Often, frustrated family members begin with, “He needs to be hospitalized.” The clinician may respond that for any emergency they should go to a hospital emergency department; otherwise, the first step is a professional assessment to identify the problem and select treatments. Parents or guardians should attend the first meeting (unless a court order separates the youth from them), and if agency workers made the contact, they should also attend.

Assessment initiates the clinician’s relationships with the adolescent patient and family and may be crucial for convincing them that treatment can help. Unfortunately, relationship-building may be lost while completing intake forms often required by insurers or governmental funding agencies. Intake workers may complete such forms before any clinical meeting to minimize that intrusion.

Assent, consent, and confidentiality

Rules vary in different jurisdictions, but before assessing minors the treating clinician must usually obtain written parental consent and assent of the minor. This starts the treatment relationship with transparency, clarifying that evaluation and treatment require agreement and participation from both patient and family. Accordingly, even if parents demand an evaluation, in many jurisdictions it cannot proceed without the minor's assent, except when ordered by a court or done under evaluation-requiring "hold and treat" statutes.

Sometimes however, parental consent may not be required. Many jurisdictions provide exceptions (SAMHSA, 2011) if the government has custody of the minor, or if the minor faces some immediate risk but parents or guardians are unavailable. Additionally, in many places the minor may consent for substance evaluations and treatment as a "mature" or "emancipated" minor. Usually, such minors are at least 16 years old and understand the planned assessment procedure.

Courts ordering substance assessments of youths charged with crimes will see resulting reports. And although American laws strongly protect the confidentiality of substance-treatment records in federally-assisted programs, those protections may not apply elsewhere. Thus, consent and assent documents must make clear what information will be available to whom, and especially, whether admitting a previously unknown crime during an evaluation will be reported to the court, or whether the court could compel its release. The documents should also clearly state that there is no confidentiality regarding child abuse or neglect, plans to harm a person, or crimes against the evaluating program or its personnel.

Who, when

The clinician is advised to assess interactions among the parents, the youth, and any involved agency worker, and also must obtain information from them separately. The next sections suggest when to see the parties together or separately, but clinicians flexibly modify these procedures according to the parties' interactions.

Chief complaint

With the parties together the clinician can ask each in turn, "Why do you think you're here to see me now." The clinician can then note, for example, disagreements ("I do *not* sneak out at night"), blaming authorities ("that judge hates us") or others ("his dead father taught him that"), hoped-for extrusion from the family ("just keep him in your hospital"), parental problems ("Dad drinks more than me"), abdication of responsibility ("they made us come"), or desperation ("With my cancer, who will look after her?" (cf., see Chapter 28)). After describing what the agency wants and planning later meetings, the agency worker may then leave.

History of the problem

The clinician can summarize those various Chief Complaints, asking, "Is that about right?" Next, it can be useful to ask about

the development of the problem, aiming eventually to know answers to the many questions outlined here and below. However, the clinician should strive for a conversational exchange, and these questions *must not* be ticked off, checklist style. This section focuses on recent events directly leading to this contact, including: problems with conduct and substances (details of the use may await the adolescent-only interview); when the problems started; their triggers; any earlier signs; the problems' progression; the parties' feelings and actions regarding the problems; arrests, court appearances, detentions, or incarcerations; and prior treatments.

Long-term goals

Having heard descriptions of the current problem, the clinician now aims both to understand the goals of the participants and to introduce them to the long-term nature of these chronic, relapsing disorders. The question commonly asked by the author is "If we do some treatment together, and if it works the way you hope, how will things be different a year from now?" This question also forces the clinician to plan not just short-term, but long-term treatment.

Developmental history

Parents provide early developmental information, but the adolescent contributes for later years. *Conception to elementary school*: Was the youth adopted? During the pregnancy, were there: prenatal care, couple's problems, maternal "need" to use tobacco or other substances, prematurity, or other difficulties? Were there problems with: the delivery or immediately after; needed extra hospitalization; feeding, colic, serious accidents or illnesses, or failure to thrive? Were developmental milestones timely? Who provided child care? Was there preschool? *During elementary school*: What were the patient's best accomplishments? Were there friends? Were there problems with grades, fighting, suspensions, fire-setting, or frequent injuries? Did the youth (compared to others) show predictors (Moffitt *et al.*, 2011) of later substance problems: discipline problems, unpredictable emotions, low frustration tolerance, assertive-rough-aggressive play, impulsive aggression, hyperactivity, inattention, impulsivity, or lack of persistence? *During middle school, and separately for high school*: Again, descriptions of best accomplishments, friends (male and female), grades, conduct or substance problems, or frequent injuries.

Considering the home environment, the clinician can ask about the family's main language and racial-ethnic identity. Who has been present in the home? How did family members relate? How did the parents supervise and discipline? Were they active in a church or other social organization? What did they do for fun? Do the parents work? Was income adequate? How often, and where, did the family move, and what schools were attended? Was there divorce, split custody, or child support? What adults came or went? Did a single parent have lovers in the home? Were social services involved? Was there arguing or

domestic violence? Were there gender-identity issues? How did the youth feel about each of these?

Family history

Were there substance-related problems in the family? More relatives with these problems predicts a more recurrent course and worse impairment (Milne *et al.*, 2009). Did relatives have anti-social or criminal problems, depression, or psychosis?

The youth's history

After excusing the parents, the author finds it useful to begin with an open-ended question, such as "Well, how do you feel about being here?" After some brief discussion, the clinician can explore the youth's views of the family. The interview considers each significant family member, as well as boyfriends or girlfriends, aiming to identify those who will help or hinder efforts to shape an abstinence-supporting environment around the patient.

The author finds it useful to ask seven introductory questions about used substances, flexibly and conversationally expanding on each with additional questions, considering the youth's unfolding history and comfort. First, *what substances do you use, and in what doses?* Which substances has the youth used, in what amounts on a typical day or week, and what is the largest single-day dose? Simple counts suffice for prescription pills, tobacco cigarettes, tubes of glue, or nitrous oxide cartridges ("whippets"). For alcohol, "standard drinks" contain similar amounts of pure alcohol, and are 45 ml. (1.5 oz.) of distilled spirits, 350 ml. (12 oz.) of beer, or 150 ml. (5 oz.) of wine. Even street measures, such as "cannabis joints (cigarettes) or blunts (cigars)" or "\$10 bags" of heroin, help estimate the intensity of use. The route of administration (swallowing, intranasal insufflation, inhalation, or injection) is important; the latter two routes more strongly drive repeated use.

Second, *when have you used the substances?* These questions address temporal patterns: age at first use, acceleration of use, periods of abstinence, the current frequency of use (e.g., doses per day, or days per week), and whether the use is steady or in binges.

Third, *where and with whom do you use the substances?* These questions seek both social reinforcement for substance use (e.g., drug parties) and dangerous drug-use environments. Does the youth usually use alone or with peers, ride or drive in cars with groups that are using, use with armed or violent peers, or with males who demand sex after providing drugs? Does the youth use substances at home, or get them from—or use with—family members?

Fourth, *how do you get the substances?* Seeking to understand the general process, while avoiding dangerous names or places, the clinician can ask: How much do you spend on substances? Have you stolen things, or sold drugs, or done sexual things for drugs or drug money? Do dealers call you?

Fifth, *what gets you to use either more or less?* Such stimuli may be certain friends or relatives, or certain moods, or doing

enjoyable things, or stressful times. Can the youth "hold" a supply of the drug, or is it quickly used up?

Sixth, *for you, what are the substances' payoffs—their good things?* Reported "benefits" often include the drug "high," the social pleasure of using with friends, a numbing of sadness, or the thrill of forbidden activities.

Seventh, *for you, what are the substances' costs—their bad things?* The clinician here can consider six categories of adverse drug effects. *Social:* Have drugs made problems with your family, or with girlfriends (boyfriends)? Have friends said they worry about you, or stopped seeing you, because of drugs? *Legal:* Were you ever stopped for driving while high, or arrested, or in court, or in detention or probation because of substances? *Educational-vocational:* Were you high in class, or did you ditch school, or skip homework because of drugs? Have you failed a drug test for work, or were you "high" at work, or missed work, or got fired because of drugs? *Medical:* Did you ever inject drugs? Did getting high, or stopping suddenly after using for a while, ever give you physical problems, like shaking, or getting agitated, or sweating, or heart pounding, or having a seizure, or passing out, or anything else? *Psychological:* Did drugs ever mess up your thinking, or hurt your mood or emotions? Are you ever sad about drugs? *Financial:* Have you borrowed money that you could not repay because of drugs?

This section concludes with any additional questions needed to determine a diagnosis. In some settings it can be useful to assess, for each substance, which DSM-5 SUD criteria have been met in the last year.

Abuse and neglect

Adolescent patients with SUDs are four times more likely than controls to report abuse or neglect, and patients' severity of maltreatment correlates significantly with the severity of their substance, conduct, and depressive problems (Crowley *et al.*, 2003), so abuse-neglect assessments are critical. "Rating Scales and Structured Interviews," below, and Chapters 29–30 recommend procedures for these assessments. Maltreatment must be immediately reported to appropriate authorities.

Suicide

SUD is a strong risk factor for suicide, and all SUD patients must be assessed for this risk (cf., see Chapter 64).

Withdrawal

Most adolescents with SUD do not develop medically dangerous withdrawal syndromes, probably because their dosing has been briefer and less steady than that of many adults. However, some who have used alcohol, sedative-hypnotic, or anxiolytic drugs with frequent high dosing for days or weeks may develop sweating, muscle twitches and jerks, or changes in vital signs or state of consciousness. These signs require medical detoxification with pharmacologic intervention. Similarly, opioid withdrawal requires medical treatment. Finally, abruptly terminating sustained, regular dosing with cannabis, caffeine,

stimulants, or tobacco produces substance-specific withdrawal syndromes (American Psychiatric Association, 2013); while rarely dangerous medically, their aversiveness may motivate resumed drug use.

Initial summary

With the patient and family together the clinician may find it useful to spend time summarizing key points, first addressing any necessary emergency actions to prevent serious withdrawal syndromes, overdose, suicide or self-injury, abuse or neglect, violence, illegal acts, dangerously intoxicated behaviors, sexually transmitted disease, or pregnancy. To initiate a treatment alliance, the clinician can again summarize the parties' Chief Complaints, emphasizing any agreements about needed changes. While respecting the patient's confidentiality, the clinician refers to the adolescent's lists of drug "payoffs," and "costs," suggesting that the patient, the parents, and the treatment team work together to eliminate drug "costs" by trying abstinence, while exploring non-drug ways to obtain the "payoffs" that drugs offered.

After discussing that, the clinician can propose a few simple, short-term goals (e.g., "being abstinent and safe for the next week") and an initial treatment venue appropriate to the risk that the patient faces (e.g., outpatient, day-treatment, residential care, or hospital). Finally, in the author's clinic, the clinician obtains consents and assents to contact involved professionals.

Coexisting disorders

As noted earlier, behavioral disinhibition involves substance and conduct problems, hyperactivity, impulsivity, inattention, and novelty-seeking. Thus, many youths with SUD also meet criteria for conduct disorder (see Chapter 65) and disorders of attention and activity (see Chapter 55), while their risky behaviors often produce traumatic experiences and post-traumatic stress disorder (see Chapter 59). Major depressive disorder (see Chapter 63) is common in adolescents with SUD, especially females, and anxiety disorders (see Chapter 60) also occur. Accordingly, clinical programs addressing adolescent SUD must routinely assess, and provide onsite treatment, for these disorders.

Rating scales and structured interviews

These tools, administered by non-doctoral clinicians, provide standardized descriptions of clinical signs, symptoms, and disorders (see Chapter 33). In large treatment programs they help supervising psychiatrists or psychologists determine diagnosis and clinical severity.

In structured diagnostic interviews a technician or computer exactly presents questions needed to establish diagnoses, recording the answers. On these assessments most adolescents entering treatment for SUD and conduct problems provide valid information for diagnosing, and for rating the severity of, their conditions, although some clearly dissemble (Crowley *et al.*, 2001). Depression and ADHD are unusually common among these patients, and their self-ratings of *severity* for those disorders also are reasonably valid. However, these patients' self-reports

in structured interviews for *diagnosing* either major depression or ADHD often are invalid in adolescents with SUDs; validity improves when parent reports supplement the self-reports, but some parents of these troubled patients refuse such interviews. At the time of this writing, relevant diagnostic interviews are based on DSM-IV and will need some revision for DSM-5.

Several structured abuse-neglect interviews are available (cf., see Chapters 29, 30). The author's is free, includes substance-focused issues (e.g., parents sharing drugs with their children), and is validated specifically for adolescents in substance treatment (Crowley *et al.*, 2003, 2013).

Well-validated clinical rating scales completed by parents, teachers, and/or the patient usefully assess the severity of, for example, depression, delinquent behavior, hyperactivity, or sensation-seeking in adolescents with SUD (see Chapter 33; Crowley *et al.*, 2001). Additionally, the number of DSM-5 diagnostic criteria met, indexes the severity of each SUD (Hasin *et al.*, 2013).

Physical investigations

SUDs produce physical findings. First, SUDs are usually associated with recurring intoxications, and sometimes with recurring withdrawals. DSM-5 details the substance-specific physical signs of intoxication and withdrawal, some of which require medical intervention.

Drug use may leave characteristic physical stigmata. For example, intravenous drug injections produce "needle tracks" (scarred peripheral veins). Repeated inhaling of volatile solvents causes perioral or perinasal "huffer's rash." "Meth mouth" (oral dryness with extreme tooth decay) complicates methamphetamine use.

Adolescents with SUD tend to be risk-takers, and drug intoxication increases that tendency. Unprotected sex may lead to unplanned pregnancy or sexually transmitted disease, and unsterile needles spread Hepatitis C and HIV. Some adolescents with SUD also engage in prostitution. Patients doing these behaviors need assessment for these medical problems.

Drug testing

Therapists cannot respond effectively to concealed relapses, and most persons with SUD report having lied about drug use. Thus, therapists must assess abstinence with drug testing, in addition to reports from patient and family. Detailed discussions of drug testing are beyond the scope of this chapter, but two points are warranted.

Tests are available for urine, saliva, sweat, breath, and hair, but reasonably inexpensive and reliable commercial urine tests are most common in substance treatment programs. While standard amphetamine tests also detect lisdexafetamine dimesylate and dextroamphetamine, they do not detect methylphenidate. Newer "designer drugs" (e.g., synthetic cannabinoids or methylenedioxypyrovalerone ("Bath Salts")) will not usually be detected, except by special, more expensive tests. Also tests are impractical or not reliable for inhalant drugs.

Alcohol's rapid metabolism makes its detection by urine or "breathalyzer" tests unreliable. Carbohydrate deficient transferin (CDT) tests for drinking, being relatively insensitive in adolescents, are usually inappropriate. Minute quantities of alcohol metabolites (ethyl glucuronide or ethyl sulfide) from as little as one drink are detectable in urine for as long as two days, but these tests also produce false-positive findings from adventitious alcohol exposures (e.g., mouthwash, hand cleaners). Transdermal alcohol monitors, widely used with probationers, are worn under the clothing, detect alcohol in sweat, and transmit reports to a central station.

Imaging and genetic diagnostic tests currently offer no empirically supported contribution to the diagnosis or treatment of SUDs.

Importance of accurate diagnosis

Correct diagnoses are critical for predicting clinical course and planning treatment, but diagnosing substance-related disorders is complex. Ten drugs or drug classes each produce a SUD and up to 10 types of substance induced disorders, requiring precise clinical assessments (American Psychiatric Association, 2013). This makes the current classification of polysubstance misuse complex.

Treatment

Overview

Guidelines often recommend procedures to reduce dropout, improve motivation and treatment compliance, and foster a strong therapeutic alliance (Bukstein *et al.*, 2005). Such approaches include making services responsive to young peoples' needs and interests; providing services in a respectful, warm and trustworthy manner (CCQI, 2012); taking an empathetic, nonjudgmental stance; and using motivational interviewing to improve treatment readiness and enhance self-efficacy (Bukstein *et al.*, 2005). Use of contingencies such as rewards or punishments (e.g., legal sanctions) can also motivate treatment engagement and adherence. Although some providers sometimes suggest waiting until substance using and dependent individuals hit "rock bottom" to intervene, this approach is not endorsed by published guidelines (Bukstein *et al.*, 2005; CCQI, 2012) and unfortunately while waiting for substance dependent youths to hit "rock bottom" some will die.

Early intervention

Some individuals, although not meeting criteria for an alcohol use disorder, drink at levels that are associated with later alcohol-related problems (e.g., for adult-sized females, four or more drinks per day, or 8 or more per week; for males 5 or more per day, or 15 or more per week). Unfortunately, relatively few health-care providers routinely screen for such drinking patterns, and therefore providers are being trained in SBIRT, interventions that cause many adults to reduce their drinking below hazardous levels. Although SBIRT has been less-studied

in adolescents, some data suggest that brief motivational interviewing can reduce subsequent alcohol-related problems among older adolescents visiting hospital emergency departments for an alcohol-related event (Monti *et al.*, 1999) and may have a positive effect on various substance use outcomes with even a single intervention session, though the effect size in one recent meta-analyses was small ($d = 0.17$; Jensen *et al.*, 2011). Adolescent SBIRT studies are underway, and a guide for practitioners working with adolescents is freely available (NIAAA, 2011). Practice guidelines in the UK recommend extended brief intervention with motivational interviewing for those aged 15 years and older, whose substance use raises concerns but who do not have multiple or complex needs or meet criteria for SUD (CCQI, 2012). Those meeting criteria for an SUD with more complex needs may require more intensive interventions or referral to more specialized care.

Venue of treatment

The American Society of Addiction Medicine Patient Placement Criteria (Mee-Lee, *et al.*, 2001) provides a widely-used, standardized approach for determining the appropriate level of care for a given patient, using information from six dimensions: (i) intoxication/withdrawal, (ii) biomedical, (iii) emotional/behavioral/cognitive, (iv) treatment readiness, (v) potential for relapse or continued use, and (vi) recovery environment. The levels of care include: (0.5) early intervention, (I) outpatient, (II) intensive outpatient or partial hospitalization, (III) clinically managed residential or medically monitored inpatient care, and (IV) medically managed intensive inpatient. For example, a youth with SUD but minimal risk across dimensions would be managed initially in an outpatient setting, while a youth in danger from suicidality and severe withdrawal risk would need medically managed inpatient care.

Psychosocial treatments

Numerous clinical trials have addressed treatment of adolescent SUD, and major reviews of psychosocial treatments generally report near-moderate to moderate effect sizes (Waldron & Turner, 2008; Tripodi *et al.*, 2010). Waldron and Turner (2008) reviewed studies comparing major treatment modalities (e.g., family therapy compared with individual cognitive behavioral therapy (CBT) or group CBT); no modality stood out as significantly better for adolescent SUD. However, Tripodi *et al.* (2010) reported some advantage of individual over family therapy for adolescent alcohol disorders, contradicting prior recommendations that family components are an essential minimum standard for treatment of adolescent substance disorders (Bukstein *et al.*, 2005).

Considering the evidence supporting specific manualized treatments, such as Multidimensional Family Therapy, rather than broad groupings like "family therapy," Waldron and Turner (2008) found many well-established or probably efficacious psychosocial treatments for adolescent SUDs (Table 66.2). Other empirically-supported treatments are listed in the

Table 66.2 Evidence base supporting psychosocial treatments of adolescent substance abuse.

Treatment modality	Strengths of existing literature	Weaknesses of existing literature	Determination
Brief strategic family therapy (BSFT)	1, 2 ^a , 4, 7, 11	1, 2, 3	Probably efficacious ^b
Behavioral family therapy (BFT)	1, 2, 6, 7, 8	2, 4	Probably efficacious
Multidimensional family therapy (MDFT)	1, 3, 4, 5, 7, 8, 9		Well established
Multisystemic therapy (MST)	1, 2 ^c , 7, 8, 10	4 ^c	Probably efficacious
Functional family therapy (FFT)	1, 3, 4, 5, 7, 8, 9, 10		Well established
Cognitive behavioral therapy-individual (CBT-I) (with or without a component of motivational enhancement therapy)	1, 3, 5, 6, 7, 8		Well established ^d
Cognitive behavioral therapy-group (CBT-G)	1, 3, 7, 9, 10	5, 6	Well established

STRENGTHS: (1) Clinically meaningful reductions in substance use; (2) Tested and then replicated by a single research group; (3) Replicated by an independent research team; (4) Well-characterized study samples; (5) Relatively large sample sizes; (6) Good substance use measures; (7) Manual guided and/or model is well specified; (8) Adherence monitoring; (9) Adequate or longer follow up; (10) Widely disseminated or highly transportable; (11) High representation of Hispanic families.

WEAKNESSES: (1) Small effect size; (2) Small samples; (3) Limited comparison conditions; (4) No replication trials by independent groups; (5) Some studies with considerable attrition; (6) Variability in the length of treatment (i.e., 5–19 sessions).

^aSimilar, but not identical, models have been replicated by independent researchers.

^bA large BSFT multi site trial (Robbins *et al.*, 2011), conducted within the Clinical Trials Network and published after Waldron and Turner (2008), showed weak effects on drug use outcomes.

^cIndependent replication has been completed for antisocial behavior but not substance use.

^dMeta-analyses of CBT-I failed to separate from minimal treatment control (Waldron & Turner, 2008).

National Registry of Evidence-based Programs and Practices (NREPP, 2013).

Most studies address outpatient treatment of adolescent SUD. However, concerns regarding safety or non-response to outpatient treatment sometimes lead to residential treatment. Unfortunately, studies of that modality generally lack methodological rigor, including lack of randomization, lack of blinded raters, and failure to use reliable, well-validated outcome measures (Tripodi, 2009). Similarly, studies of adolescents in Alcoholics Anonymous (AA) and Narcotics Anonymous (NA) have methodological weaknesses, such as single-group designs (Sussman, 2010). However, AA and NA are recommended as adjuncts to professional treatment in the American Academy of Child and Adolescent Psychiatry's practice parameters (Bukstein *et al.*, 2005) and in adult populations 12-step facilitation appears to be as efficacious as other well-accepted psychosocial treatments.

Contingency management approaches in adolescents (Stanger & Budney, 2010) monitor target behaviors (e.g., drug abstinence) and follow them with rewards and/or punishments. Like motivational enhancement techniques, contingency management approaches can be combined with other psychosocial treatments, such as cognitive-behavioral therapy (Stanger & Budney, 2010). Because many adolescents with SUD have legal entanglements, one contingency may be criminal justice rewards and punishments (e.g., "stop using drugs or spend a week in juvenile detention"). Such approaches are sometimes formalized through juvenile drug courts, which do reduce youths' drug use and criminal behaviors beyond that seen with family courts; integration of evidence-based adolescent treatments further improves these outcomes (Henggeler, 2007).

Pharmacotherapy

Despite the many drugs misused by adolescents, alcohol, opioid and nicotine use disorders are the only ones having federally-approved pharmacotherapies in the USA. Moreover, the research literature supporting those approvals generally comes from adult studies; there are few adolescent-specific pharmacotherapy trials. Thus, the American Academy of Child and Adolescent Psychiatry's practice parameters on substance abuse note that medications may be used, but are an optional recommendation (Bukstein *et al.*, 2005).

Alcohol

Three medications are approved in the USA to treat alcohol dependence in adults. (i) Naltrexone is a mu-opioid receptor antagonist that in clinical trials reduces subjective craving, delays the time to the first drink, and reduces chances of relapse. This medication is available both as an oral preparation or as an expensive, once-per-month intramuscular injection (naltrexone XR). It must be used with caution in patients who are likely to require opioid pain management, as it blocks the effects of these medications. Also, it precipitates opioid withdrawal in persons actively using opioids. Similarly, the European Medicines Agency has approved nalmefene, another opioid antagonist, for heavy-drinking individuals; it can be used on an "as-needed" basis when cravings are high or when a lapse has occurred. (ii) Acamprosate appears to reduce CNS hyperexcitability and may increase the number of consecutive days of alcohol abstinence. Despite its support in European studies, this medication was not better than placebo in the American multi site COMBINE trial. (iii) Disulfiram is an aversive pharmacotherapy

that produces an unpleasant flushing reaction when alcohol is consumed. When provided with supervised administration (e.g., having an invested family member give the drug) this medication reduces alcohol consumption, increases the number of days abstinent, and improves alcohol-related biomarkers, such as gamma-glutamyl transferase levels. Topiramate also has mounting support for effectiveness; several other medications have been studied, but the quality of those studies varies.

Unfortunately, for adolescents the data supporting use of these medications is weak. For example, one small ($n=26$) 90-day double-blind placebo-controlled study of disulfiram among adolescents with alcohol use disorder suggested that disulfiram improved rates of continuous abstinence; no safety concerns were identified (Niederhofer & Staffen, 2003). The UK's NICE has issued a guidance document which includes detailed information on pharmacotherapy for alcohol use disorders, and discusses the prescribing of naltrexone and acamprosate for adolescents (NICE, 2011).

Opioid agonists

Opioid dependence tends to follow a chronic course, with high relapse rates after simple detoxification. Methadone is a full mu-opioid agonist which, in adult maintenance therapy, is cost-effective and reduces needle use, heroin use, medical comorbidity, and mortality. Despite some evidence for safety of methadone in persons 16–21 years old (Lehmann, 1976), in the USA those under age 18 must relapse after two detoxification attempts before qualifying for methadone treatment; that is, they must repeatedly use a potentially fatal street drug before receiving a mortality-reducing medication. Moreover, some methadone programs simply do not admit adolescents.

Buprenorphine is used in many countries for opioid maintenance therapy. This partial mu-opioid agonist is safer than methadone in overdose. A widely-used sublingual buprenorphine-naloxone combination reduces risks of injection; when taken sublingually the buprenorphine, but not the naloxone, is adequately absorbed, but if the medicine is injected the naloxone blocks mu-opioid receptors, displacing opioid agonists and prompting opioid withdrawal. Woody *et al.* (2008) randomized opioid dependent adolescents and young adults into a 12-week study. They received either a 2-week detoxification with buprenorphine-naloxone, or 9 weeks of buprenorphine-naloxone maintenance with a 3-week taper. Those maintained on buprenorphine-naloxone were significantly more likely to remain in the study at 12 weeks (70% vs 21%) and had significantly less injection drug use and use of opioids or marijuana. However, in 6-, 9-, and 12-month follow ups the groups were not significantly different in reported opioid use, marijuana use, or injection drug use; thus, 3-months of buprenorphine-naloxone treatment did not alter long-term course. The study authors suggested that, although young patients' duration of opioid dependence is relatively brief, clinicians should be in no hurry to stop this effective medication. This medication is approved in the USA for the treatment of

opioid dependence in those at least 16 years of age and by the European Medicines Agency's marketing authorization for children "over 15 years of age." The UK's NICE guidance document discusses methadone and buprenorphine for managing opioid dependence (NICE, 2007a).

Opioid antagonists

One alternative to agonist maintenance treatment of opioid dependence is antagonist maintenance with naltrexone, which blocks the effects of an opioid dose. A guidance document on naltrexone for opioid dependence has been released by the UK's NICE (NICE, 2007b). This medication induces opioid withdrawal symptoms in active users, so it is generally started 7–10 days after the last opioid use. Studies in adults suggest poor treatment retention with this medication, except when strong contingencies motivate participation; examples are physicians who must take the medication to retain their medical licenses, or persons who take it as a condition of parole. Some data do suggest promising results with long-acting naltrexone XR and naltrexone subcutaneous implants. One multisite comparison of naltrexone XR and buprenorphine is underway and will help identify the relative merits of each approach. Again, there are few treatment studies among adolescents, but one uncontrolled case series of 16 adolescents and young adults using naltrexone XR reported encouraging results (Fishman *et al.*, 2010).

One randomized trial of 36 adolescents examined detoxification of opioid dependent youths before transitioning them to naltrexone. During opioid detoxification, buprenorphine, compared to clonidine, resulted in higher treatment retention through the detoxification (72 vs 39%), more opioid-free urine tests (64 vs 32%), and a higher likelihood of naltrexone induction (61 vs 5%) (Marsch *et al.*, 2005).

Nicotine

Some patients think that they are more likely to abstain from illicit drugs or alcohol if they continue using cigarettes, but empirical evidence in adults indicates that smoking cessation interventions improve other substance treatment outcomes. Three main pharmacological treatments for nicotine dependence are currently available: nicotine replacement therapy (NRT), bupropion, and varenicline. NRT is delivered in numerous ways, including a skin patch, chewing gum, or an inhaler. Then, dosing usually is tapered, often stepwise, over months. Bupropion, which also has antidepressant effects, is usually started at 150 mg and increased after about 3 days to a target dose of 300 mg/day. Patients are instructed to set a quit date within the first 2 weeks on medication. Varenicline doses are raised over the first 8 days to a target of 1 mg orally twice per day, with medication starting about 1 week prior to the patient's scheduled quit date. Some evidence supports a larger effect size for varenicline compared to bupropion, but post-marketing surveillance has raised concerns about suicidality, mood changes, and a small increase in cardiovascular events with varenicline.

Again, evidence on pharmacological treatments of adolescent nicotine dependence is sparse, but NRT and bupropion, alone or in combination, are well tolerated (Killen *et al.*, 2004; Moolchan *et al.*, 2005; Muramoto *et al.*, 2007). There is evidence of efficacy in adolescents for NRT delivered as a patch (Moolchan *et al.*, 2005), and for bupropion at the 300 mg/day dose, at least in the short term (Muramoto *et al.*, 2007). A small (total $n = 29$), uncontrolled 8-week trial of bupropion XL (once-daily dosing to reduce problems of medication adherence) and varenicline (standard dosing for those weighing at least 55 kg and lower doses for those under 55 kg) among 15–20 year old smokers did not raise safety concerns, and both medications were associated with significant reductions in daily cigarette use (Gray *et al.*, 2012). A larger adolescent study of varenicline currently is underway. The UK's NICE has also published a guidance document including information on smoking cessation which suggests use of NRT but not bupropion or varenicline for those under 18 years of age (NICE, 2008).

Blending treatments and treatment matching

Some psychosocial treatment studies combine approaches (e.g., motivational enhancement therapy or contingency management with cognitive-behavioral therapy), but evidence for blending techniques from various evidence-based treatments still remains limited. However, Anton *et al.* (2006) combined elements of motivational enhancement, cognitive-behavioral therapy, community reinforcement and 12-step facilitation treatments into a single psychosocial intervention for adults with alcohol use disorder; to our knowledge such combinations have not been tested in adolescents. In addition, empirical research provides little guidance for matching particular patients with particular treatments. However, in some instances common sense may suggest the most appropriate approach. For example, an emancipated youth who is working and living independently might respond less well to family-centered treatment.

Working with criminal justice and social service agencies

Some clinicians worry that working closely with probation, parole, or social-service agencies may damage the treatment alliance, but legal contingencies can be important treatment motivators. When patients are referred through such agencies, it is important to discuss how and what information will be shared, and to complete appropriate release forms (see Section titled Assessment). Teamwork with such referring agencies can help to mobilize systemic supports that improve the likelihood of treatment compliance, abstinence from drug use, and better long-term outcomes (for general information on legal issues in the care and treatment of children with mental health problems, see Chapter 19).

Relapse prevention

Even highly motivated SUD patients may relapse. Although some patients, or even providers, view relapse in catastrophic

terms (e.g., a sign that a patient has learned nothing), relapse prevention techniques reframe relapse as an opportunity to extend treatment gains. Briefly, relapse prevention procedures identify high risk situations, including certain people, places, or emotional states; use planning to anticipate and reduce contact with those situations; and when they cannot be avoided, teach substance-free coping with the situations (Hendershot *et al.*, 2011). Such models are broadly incorporated into psychosocial treatments of substance disorders.

Treatment of co-morbid mental health disorders

The American Academy of Child and Adolescent Psychiatry's Practice Parameters state that assessment and treatment of co-morbid psychiatric disorders are a minimal standard of care, supported by substantial empirical evidence and "overwhelming" clinical consensus (Bukstein *et al.*, 2005). Standard treatments for co-morbid disorders are outlined in other chapters of this text, but five important principles apply here. (i) Although disentangling substance-induced and independent mental health symptoms may be complicated, examining the temporal inter relationship of symptoms, the age of symptom onset, and the persistence of symptoms during periods of abstinence is helpful. Some authors use a timeline approach to guide such inquiries (Riggs & Davies, 2002). (ii) Although sequential treatment (e.g., requiring remission of substance use before treating depression) is sometimes recommended, concurrent treatment of both disorders is presumed to be optimal (Bukstein *et al.*, 2005). (iii) Medications for some disorders, including stimulants for attention-deficit/hyperactivity disorder, may be abused. In youths with SUD the risks and potential harms from such treatments must be weighed against potential benefits, especially since non-stimulant alternatives are available. (iv) Adolescents with SUD may experiment with medications prescribed for comorbid disorders, seeking a "high." As exemplified by bupropion's risk of seizures, such experiments can be dangerous. Having parents safely store the medication and monitor administration may reduce such risks. (v) Although a large body of empirical research focuses on treating adolescents' mental health disorders, the specialized literature on treating the co-morbid mental health disorders of adolescents with SUD must be considered (e.g., Riggs *et al.*, 2007).

Non-substance "behavioral addictions"

Gambling disorder in DSM-5 replaces DSM-IV's more pejorative term, "pathologic gambling." Gambling disorder is found in the same chapter as substance related disorders because the conditions have somewhat similar diagnostic criteria and may share certain genetic and neural mechanisms (Petry *et al.*, 2013). DSM-5 also somewhat altered the diagnostic criteria. The prevalence of adolescent problem gambling exceeds that in adults (Forrest & McHale, 2012), and gambling problems in adolescents are associated with frequent substance use and

other risky behaviors (Proimos *et al.*, 1998). This comorbidity of substance and gambling problems suggests screening adolescents with SUD for gambling disorder, using an available screen (Forrest & McHale, 2012).

DSM-5's drafters found insufficient evidence (Hasin *et al.*, 2013) to establish diagnoses for "addiction" to shopping, exercise, or sex, as some had proposed. However, "internet gaming addiction" was placed into a section of DSM-5 reserved for conditions that future research might establish as disorders.

Future developments and necessary research

Great progress has been made in defining early risks for adolescent SUDs, as well as methods for prevention, early intervention, and treatment of the disorders. Further advances are needed in the following areas: Some children's pre-pubertal behavioral disinhibition suggests a risk for future SUD, and those children need studies of empirically-supported, focused prevention efforts. SUD is a chronic relapsing and remitting problem, requiring multi year studies of psychosocial and pharmacological approaches for adolescents with SUD, including controlled studies of long-term court-required case-management and treatment for relapsing youths. Research on medication treatments for adolescent SUD is sorely needed. Shifting drug policies, including legalization of marijuana in some jurisdictions, cry out for studies of the effects of such policies on drug use and SUDs in adolescents. Better identification of biological contributors to these life-threatening disorders could lead to new, targeted, and more effective treatments; focuses should include identifying genomic risk factors, together with imaging of: brain-based antecedent risks for substance involvement, drug-induced brain pathology, and brain changes from treatment.

Disorders of personality

Jonathan Hill

School for Psychology and Clinical Language Sciences, University of Reading, UK

Why is something like the concept of personality disorders needed?

The personality disorders are described within a framework of adult psychiatric diagnoses that makes a distinction between disorders that are episodic, with clear onsets and offsets and circumscribed symptomatology, for example depression, and disorders that are more enduring with widespread emotional and behavioral problems. The need for something like the concept of personality disorder arises then in two main ways. First, some individuals have behavioral and emotional problems that precede and extend beyond the confines of episodic disorders. Second, these problems share with personality traits (habitual patterns of behavior, thought, and emotion) the characteristics of being relatively enduring and evident in many situations. The concept was developed to be applied to adults and so inevitably much of the relevant research considered in this chapter has been carried out with adults. However, the discussion in this section regarding the need for the concept applies equally during adolescence. It is also important to adopt a developmental perspective as the vulnerabilities and precursors of personality disorder have their origins in childhood.

The child and adolescent context in which we might consider the concept of personality disorder is however very different from that of the adult. Disorders that tend to persist are common, notably the disruptive behavior disorders (DBDs) of oppositional defiant disorder (ODD) and conduct disorder (CD) (see Chapters 4 and 65), attention-deficit hyperactivity disorder (ADHD; see Chapter 55) and autistic spectrum disorders (ASD; see Chapter 51). These are not however thought about in the same way. Disruptive behavior problems arising in young children are associated with many adverse psychiatric and social outcomes in later life, some of which are summarized in the adult antisocial personality disorder (ASPD) diagnosis. By contrast (ADHD) and autism spectrum disorder (ASD),

which also show persistence into adult life (see Chapter 3), are not viewed as personality disorders either in children or adults. What they are called probably does not matter, but differentiating them is crucial. The key point for the clinician is that before puberty each of these disorders may need to be considered for some presentations, for example, of peer aggression, while in adolescents at least one additional grouping of persistent and pervasive problems, summarized as borderline personality disorder (BPD), also enters into the differential diagnosis.

In clinical practice, in adolescence the concept is often relevant where the presenting problem can be diagnosed as an episodic disorder such as depression, but there are additional features that are not accounted for by that diagnosis, nor by an accompanying “comorbid” episodic disorder such as generalized anxiety disorder. Thus the key is the extensiveness or the diversity of the difficulties. In general, consideration of personality disorder will require also that these, or similar, difficulties were present before the onset of the disorder. Furthermore as the presenting symptoms resolve, those attributed to personality disorder persist. The concept is also relevant where an individual has problems that are severe enough to cause distress to themselves or others, and impair daily functioning, but they do not follow the pattern of episodic disorders. Examples include repeated violence, or self-harm in the absence of diagnosable depression, or difficulties in social role performance, for example in work or close relationships.

Current conceptualizations of personality disorder and diagnostic and statistical manual (DSM) IV and 5

The World Health Organization (1996) classification, ICD-10, makes a basic differentiation between organic personality disorders (meaning those resulting from severe head injury,

encephalitis, and other forms of overt brain damage); enduring personality changes deriving from some catastrophic experience, personality abnormalities that reflect the residue of some mental illness (e.g., residual schizophrenia) and what they term personality disorders. The American Psychiatric Association (2000) scheme makes broadly comparable distinctions. This chapter is concerned with this last group of specific personality disorders, because the others have only an extremely limited application in childhood and adolescence.

There are 10 key adult personality disorders outlined in Table 67.1. It should be borne in mind that the concept of personality disorder did not originate from a model of normal personality, and indeed descriptions of different personality disorder types have come about through several contrasting routes. First, there are those that derive from the clinical observation that there are individuals who show enduring patterns of inflexible and seriously maladaptive behavior that seem to fall outside the traditional criteria for mental illness or psychiatric syndrome. The need to have a term to describe these patterns of abnormal behavior led to the concepts of psychopathy put forward by writers such as Hare (1970), Henderson (1939) and Cleckley (1941). Second, there are the categories of personality disorder that identify individuals who are thought to be most prone to suffer from episodic mental disorders. Schneider's (1923, 1950) notion of psychopathic personality (defined quite differently from the psychopathy formulations of Hare, of Henderson, and of Cleckley) provides the main historic notion of this approach. Many of the ICD-10 specific personality disorder categories (e.g., paranoid, anankastic, and anxious) represent this tradition (World Health Organization, 1996). Third, some categories have their origins in empirical observations of the continuities between psychopathological disorders in childhood and pervasive social malfunction in adult lifestyle. The DSM diagnosis of ASPD is the obvious example of this type, with its starting point in the findings of the long-term longitudinal studies pioneered by Robins (1966, 1978). Fourth, some categories stem fairly directly from theoretical, especially psychoanalytic, notions. The concept of borderline personality organization (Kernberg, 1967, 1975) underlies specification of the DSM diagnosis of BPD (Gunderson *et al.*, 1981). Finally, a few categories have come, at least in part, from genetic findings. Meehl (1962) coined the term schizotypy to describe the postulated characteristics of schizophrenia-prone individuals. The Danish adoption study showed that the biological families of adopted schizophrenic probands included a raised rate of personality disorders that seemed to exhibit some features reminiscent of schizophrenia (Kety *et al.*, 1971). Spitzer *et al.* (1979) developed more explicit criteria for this type of personality syndrome which has come to be termed schizotypal personality disorder (SPD). There is now substantial support for a genetic relationship between SPD and schizophrenia, based on studies of families, twins, and adoptees (Cannon *et al.*, 2008).

Table 67.1 The characteristics of 10 key personality disorders.

Paranoid Personality Disorder

Pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts.

Schizoid Personality Disorder

Detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts.

Schizotypal personality disorder

A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood and present in a variety of contexts.

Antisocial personality disorder

A pervasive pattern of disregard for and violation of the rights of others in adult life that is preceded by conduct disorder characterized by features such as law breaking, deceitfulness, aggressiveness, reckless disregard for safety, irresponsibility and lack of remorse.

Borderline personality disorder

Pervasive instability of interpersonal relationships, self-image and affects, and marked impulsivity beginning by early adulthood.

Narcissistic personality disorder

Pervasive grandiosity (fantasy or behavior), need for admiration, and lack of empathy in a variety of contexts.

Histrionic personality disorder

Pervasive excessive emotionality and attention-seeking present in a variety of contexts.

Dependent Personality Disorder

Pervasive, excessive need to be taken care of, accompanied by submissive and clinging behavior and fears of separation.

Avoidant personality disorder

Pervasive social inhibition, feelings of inadequacy, and hypersensitivity to negative evaluation.

Obsessive compulsive personality disorder

Preoccupation with orderliness, perfectionism and mental and interpersonal control. This comes at the expense of flexibility, openness and efficiency and is present in a variety of contexts.

Even if a general concept does not cover all of the personality disorders, it is relevant to two that commonly need to be considered in adolescent clinical practice: antisocial and borderline personality disorders. The complexities and difficulties in nailing a general concept are illustrated in the debate over proposals made for DSM-5. In DSM-IV (American Psychiatric Association, 2000) the core dysfunction is described as "An enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture. This pattern is manifested in two (or more) of the following areas: (i) Cognition (i.e., ways of perceiving and interpreting self, other people and events), (ii) Affectivity (i.e., the range, intensity, lability, and appropriateness of emotional response), (iii) Interpersonal functioning, (iv) Impulse control." Although ultimately DSM-5 retained the approach used in DSM-IV for defining personality disorders, this decision was only made

after extensive attempts to generate an alternative definition that incorporated extensive information on personality structure in both health and illness. To seek such a definition, an alternative set of proposals involving a dimensional–categorical model was discussed. These proposed revisions were included in a separate, supplemental chapter in DSM-5 as a basis for future research into ways of characterizing the personality disorders in clinical practice. In these alternative proposals for DSM-5 (American Psychiatric Association, 2013) the core deficit in personality disorders was described as, “... impairments in personality (self and interpersonal) functioning and the presence of pathological personality traits.” To diagnose a personality disorder using these proposals that were eventually not adopted, the following criteria must be met: “A. Significant impairments in self (identity or self-direction) and interpersonal (empathy or intimacy) functioning. B. One or more pathological personality trait domains or trait facets.” Unlike personality disorder definitions in DSM-IV and the main section of DSM-5 that emerged from data on patients, these alternative trait domains were linked to research on personality structure, manifest in various populations. These definitions, drawn from factor analytic approaches to personality, which are outlined later in the chapter, consisted of *negative emotionality*, *introversion*, *antagonism*, *disinhibition*, *compulsivity* and *schizotypy*. In clinical and research practice, DSM-IV and DSM-5 personality disorders retain definitions in place since the 1990s, as identified by the criteria summarized in Table 67.1. As discussed, after extensive review, the DSM-IV approach with the same 10 personality disorders has been retained in DSM-5.

Key questions

The differences between definitions in DSM-5 that were retained from DSM-IV and the alternative proposal that was not accepted for the DSM-5 revision illustrate how profound are the uncertainties in the field of personality disorders, and indicate the challenge to clinicians in talking with patients and their families. This is not only a question of how to diagnose, but also how to formulate complex presentations. Four topics that may help conceptualize formulations are discussed here.

How should personality disorder be specified and explained?

DSM-based specifications vary in the extent to which they differentiate between manifestations and underlying processes. ASPD is almost entirely specified by deviant behaviors such as criminality, violence, impulsive actions, and failures to maintain adult social roles. This is a level of description that makes clear what needs to be explained and makes no reference to what the explanation may be. By contrast, BPD is specified by a mixture, both between and within items. Thus the item “repeated self-harm” is clearly a behavioral pattern for which a range of explanations may be sought, while “identity disturbance: markedly and persistently unstable self-image or sense of self”

refers to psychological processes that may explain behaviors. The item, “A pattern of unstable and intense interpersonal relationships characterised by alternating between extremes of idealization and devaluation” describes both behaviors and states of mind.

A focus on behaviors as opposed to underlying processes influences both research and clinical practice. Where only the behaviors are specified, research questions can be framed with many possibilities in mind. This becomes problematic where potential explanatory variables are included in the definition, as these are more difficult to assess than overt behaviors. The clinical implications are very similar. A behavioral description can establish the extent of the problem, leading to enquiry that explores a range of possible explanations, for which different assessment tools may be required. On the other hand, a specification of personality disorder confined to behaviors may fail to specify a distinctive process such as idealization and devaluation in relationships, and hence be over- or under-inclusive, and so clinically less informative.

The way forward may be to proceed more cautiously and systematically from specification of behavioral dysfunction to explanation. This is the approach taken using the Adult Personality Functioning Assessment where personality functioning is assessed as social role performance in six social domains over a 5-year period. This is consistent with studies of adult personality disorders that find strong associations with social dysfunction (Hill *et al.*, 2000; Seivewright *et al.*, 2004; Skodol *et al.*, 2005) and “the characteristic that seems to define them all is a pervasive persistent abnormality in maintaining social relationships” (Rutter, 1987). Crucially, personality disorders may remit while social dysfunction persists, suggesting that it is core to the disorder (Gunderson *et al.*, 2011). The forms of social dysfunction may provide clues to specific processes. For example, one of the characteristics of the social dysfunction of BPD is a problem in maintaining a demarcation between the behaviors and emotions that belong with different kinds of social interaction (Hill *et al.*, 2008). This is discussed further later in the chapter.

Normal personality or personality disorders?

It would make sense if the areas of dysfunction identified in the personality disorders could be specified in terms of the functions served by normal personality. This is not the case in DSM-5 however, in part because, as outlined earlier, different personality disorders have been formulated for different reasons, but also because the conceptualization of personality remains problematic. The Five Factor Model (FFM) has been widely advocated as a solution. The FFM has been derived from studies using predominantly self-report measures with items derived from lexical analyses. The basic premise of this approach is that common linguistic descriptors, such as “hopeful” or “worried” have been retained in languages because they map on to personality characteristics (Widiger & Lowe, 2007; Widiger & Costa, 2012). Items generated from lexical analysis

are subjected to factor analyses yielding five factors that capture substantial proportions of personality variations, Extraversion/Positive Emotionality, Neuroticism/Negative Emotionality, Conscientiousness/Constraint, Agreeableness, and Openness-to-Experience. The five factor solution has been widely replicated; it shows cross-cultural consistency; and the factors show stability over time in line with most concepts of personality (Widiger & Costa, 2012). The personality disorders, conceptualized in relation to these personality factors, arise from maladaptive extreme variants of common personality traits. In discussions of models such as these, two issues are commonly conflated, whether categorical or dimensional approaches are more useful and the definition of “normal personality functioning.” The categorical versus dimensional dilemma is discussed later in the chapter. Definition of normal personality function remains a matter of debate. Long-standing critiques have highlighted only modest agreement between self and informant reports, differences between self-report and observed behaviors, and cross-situational differences, as limitations (Mischel, 2004).

Historically, the various conceptualizations of personality disorders have often been presented as competing. However, at this stage in our understanding, it may be more helpful to view the general rubric of personality disorder as identifying a number of related dysfunctions whose importance depend on what needs to be explained. Studies that make use of measures from the different traditions are therefore particularly illuminating. For example in a follow up of the Collaborative Longitudinal Personality Disorder Study of psychiatric patients, DSM-IV categorical and dimensional variables, and dimensions of the FFM, all predicted a range of outcomes over up to 10 years, including suicidal behaviors, occupational and interpersonal functioning, and depression (Morey *et al.*, 2012). In relation to some personality disorders, notably borderline and antisocial disorders, DSM-IV items, and FFM traits each added to the prediction of outcomes, although in others such as histrionic disorder the DSM items did not add to the prediction over FFM traits.

How do developmental perspectives on personality and its disorders help?

Commonly, vulnerabilities or precursors of personality disorder can be identified in childhood and so there are good reasons to review the adequacy and relevance of theories of personality from a developmental perspective (see Chapter 8). First, how coherent or homogenous are the hypothesized traits? Although the big-five are characterized as “higher-order,” each includes “lower-order” traits, some of which differ substantially. This issue is reviewed by Caspi *et al.* (2005). For example, the higher-order trait neuroticism is well validated and highly predictive in childhood and adult life, but includes both proneness to fear and to anger. These different emotions motivate different behaviors, they are mediated via different neurological substrates, and they have different implications

for development and psychopathology (Lemerise & Arsenio, 2000; Frick & Morris, 2004). Developmental hypotheses for disruptive behavior problems (see Chapters 4 and 65), the childhood antecedents of ASPD, envisage increased risk arising from elevated anger proneness, but reduced fearfulness (Smeekens *et al.*, 2007; Colder *et al.*, 2002). Second, some of the personality traits also resemble temperamental characteristics. Thus, fear proneness and anger proneness are two aspects of temperament commonly assessed in infancy (Robinson & Acevedo, 2001). More generally the overlap between temperament and personality traits requires further attention (Caspi *et al.*, 2005). Third, FFM personality traits are determined by the frequency of behaviors across context and time. However, traits can be conceptualized in other ways. In particular, individuals can be characterized by predictable and patterned differences in their behaviors across situations, arising for example from the interplay between social information processing and context (Mischel, 2004). Fourth, personality development entails the development of the person as social organism. Personality traits such as neuroticism undoubtedly influence social relationships (e.g., Robins *et al.*, 2002), but there are also aspects of personality functioning such as ways of interpreting others' behaviors that are inherently social and entail dedicated neuronal networks (Johnson *et al.*, 2005). The capacity to regulate behaviors and emotions according to the demands of different kinds of social domain, for example contrasting teachers and parents, is key to effective personality development (Hill *et al.*, 2010). Fifth, personality develops in interaction with the environment so that its features are likely to reflect more or less successful adaptations rather than any simple manifestation of stable traits.

It could be argued that to be of real value, developmental perspectives should generate alternative formulations. There is no doubt that developmental findings inform understanding of personality disorders, most notably in the case of ASPD being preceded by disruptive behavior problems (see Chapter 65). Risks accumulate and are moderated by the interplay between the child's biology and psychology (Hill, 2002). Furthermore some key developmental processes clearly have implications for personality disorders. The child's organisation of emotions and behaviors provides an illustrative example. Initially, interactions are confined to caregivers, but in the second year, the interpersonal world begins to encompass other children and adults. However, the developing child does not interact in the same way with these different groups. This is seen strikingly with the emergence of stranger anxiety and selective attachments between 6 and 9 months. In the presence of a stranger, most children become wary and seek comfort from a caregiver. Later, as sibling and peer interactions develop, further differences are apparent. Children play with other children, and distinguish friends from non-friends, but rarely turn to other children for comfort as they do with familiar adults (Rubin *et al.*, 1999). Thus, individual development entails an increasingly sophisticated organisation of the child's behaviors. This requires not only the organization of behaviors, but also a

recognition of the particular goals, problem solving procedures and social resources available in each kind of social interaction. These contrasting types of social interaction have been described as social domains, each with its own underlying rules or “algorithms of social life” (Bugental, 2000). The hypothesis that domain organization is a key element in personality development leads also to the prediction that problems in domain organisation may be found in personality disorders (Hill *et al.*, 2010).

Validation

Stability and associations with episodic disorders

It is assumed that personality disorders show substantial stability over time. However, several studies have found low to moderate stability (e.g., Ferro *et al.*, 1998). In a follow-up every 2 years, of 290 patients meeting DSM-IV criteria for BPD, 74% had remitted after 6 years, and only 6% had remitted and then relapsed (Zanarini *et al.*, 2005). After 16 years, almost all of the borderline patients no longer met DSM criteria (Zanarini *et al.*, 2012). The picture was however different for social dysfunction, where around 50% of patients had significant social problems at 16-year follow-up (Zanarini *et al.*, 2012), findings echoed in other research on social dysfunction (Rutter & Quinton, 1984; Quinton *et al.*, 1995; Seivewright *et al.*, 2004). The distinction between episodic disorders, such as depression, and personality disorders was enshrined in DSM-IV Axis I and Axis II. However, findings on remission and persistence in personality disorders raised questions on this dichotomy, and the distinction between Axis I and Axis II disorders no longer appears in DSM-5.

Co-occurrence of personality and episodic disorders is common. Risk for depression or other episodic disorders may be increased by personality disorder through poor coping and hence helplessness (Vollrath *et al.*, 1994), or increased life events associated with poor interpersonal functioning (Daley *et al.*, 1998). Episodic disorders may create the conditions in which personality disorders develop because a chain of maladaptive behaviors and adverse environmental responses is set in motion (Kasen *et al.*, 1999). Both environmental and genetic influences may contribute to co-occurrence. Many of the effects of child maltreatment on adult psychiatric disorders are nonspecific, and they probably contribute jointly to risks for personality disorders and conditions such as drug abuse and depression (Widom *et al.*, 2009). Malone *et al.* (2004) assessed ASPD and alcohol dependence in 289 twin pairs at ages 17, 20, and 24. There were moderate genetic influences on each disorder at each age, and a substantial proportion of these influences was common to the two disorders.

It might be expected that, whatever the relationship between episodic disorders and personality disorder, the combination should in some sense reflect a more severe variant, with implications for treatment outcome. Individual studies have commonly

failed to find an association. However, in a meta-analysis of all depression treatment studies in which personality disorder had been assessed, personality disorder was associated with a doubling of the risk of a poor outcome for depression (Newton-Howes *et al.*, 2006). The authors suggest that many individual studies report nonsignificant results because they have inadequate statistical power to detect a difference of this size. Furthermore, treatment outcomes may be related to overall severity of personality disorder symptomatology, and may be affected by some, but not other, disorders (Levenson *et al.*, 2012). Very little is known about the ways in which personality disorder may be associated with a poor outcome. Possibilities include that it may be associated with poor treatment compliance, or with greater severity of overall psychopathology, or with more psychosocial adversities and fewer interpersonal resources.

Differentiation among personality disorders

The ICD classification specifies nine personality disorder types, and the DSM system, 10. To a certain extent, the different categories reflect the different origins referred to earlier. The DSM classification, shown in Table 67.1, has received much attention; evidence for discriminant validity is not strong. Consistently, studies have shown that individuals who receive one personality disorder diagnosis often receive several (Pfohl *et al.*, 1986; Morey, 1988; Oldham *et al.*, 1992). There is evidence that the DSM categories cluster into three broad bands of: the odd/eccentric (A), the dramatic/emotional/erratic (B), and the anxious/fearful (C) (Kass *et al.*, 1985). However, personality disorders also often cross these bands (Oldham *et al.*, 1992).

Support for the discriminant validity could arise from differential association with other psychiatric conditions, family-genetics, or prognostic differences. Studies of the association of BPD with other episodic and personality disorders have provided some support for its discriminant validity. Zanarini *et al.* (1998) compared patients with BPD and patients with other personality disorders. Those with borderline disorder had higher rates of associated paranoid, avoidant, and dependent personality disorders, and higher rates of mood, anxiety, and eating disorders.

The most clear-cut finding from family studies is the association between schizophrenia and SPD (Kendler *et al.*, 1981; Kendler *et al.*, 1984). A significant but weaker association with schizophrenia has been found with paranoid personality disorders (Kendler & Gruenberg, 1982; Kendler *et al.*, 1985). There is consistent evidence for genetic influences on adult antisocial behaviors (e.g., Langbehn *et al.*, 1998), but not adult violence (Carey & Goldman, 1997). Genetic studies also provide support for both general effects and for groupings of personality disorders. For example, a twin study of 2794 adults demonstrated distinctive genetic and environmental factors with both general and specific effects (Kendler *et al.*, 2008). It identified three genetic factors, one with high loadings on PDs from all three

DSM clusters, one for borderline and antisocial and one for schizoid and avoidant disorders.

Most studies of the association between adverse childhood experiences and personality disorders have reported associations with a wide range of episodic and personality disorders (e.g., Johnson *et al.*, 1999), which could reflect either genetic or environmental influences (Bornovalet *et al.*, 2013). Nevertheless specificity with particular disorders would support their validity. Bezirganian *et al.* (1993) found that the combination of maternal inconsistency and high maternal over-involvement assessed in adolescence was associated with the persistence or emergence of BPD, and no other episodic or personality disorders. Parker *et al.* (1999) reported that dysfunctional parenting in childhood was associated with the dramatic and anxious DSM clusters, but not the odd/eccentric cluster. In the twin study of Kendler *et al.* (2008) each of three environmental factors had high loadings on Clusters A, B, and C respectively.

Categorical versus dimensional characterizations of personality disorders

Diagnostic systems treat psychopathology as a categorical entity. However, data fail to find natural cut offs demarcating disorders from health (Pickles & Angold, 2003) (see also Chapter 2). Most early studies treated personality disorders as categories, but the advantages of dimensional approaches are becoming increasingly apparent. Evidence for validity generally is stronger for dimensional methods. Personality disorder symptoms scores show greater stability than diagnoses (Skodol *et al.*, 2005) and there is a greater elevation of borderline symptoms than BPD diagnoses in the first degree relatives of patients with BPD (Zanarini *et al.*, 2004). In the 10-year follow-up of patients in the Collaborative Personality Disorder Study, dimensional variables, both DSM and FFM based, provided superior prediction of functioning compared to DSM personality disorder categories (Morey *et al.*, 2012). Diagnoses may also lump together symptoms that reflect different processes. Zanarini has suggested that BPD comprises acute symptoms that wax and wane and may be affected by life events, and others that are chronic or “temperamental” (Zanarini *et al.*, 2005). Such a proposal requires further investigation but does illustrate advantages to dimensional frameworks. In community studies, increasing personality disorder symptoms below diagnostic threshold are associated with increasing social dysfunction (Daley *et al.*, 2000). This is important clinically because it suggests that even among patients who do not meet criteria for a diagnosis, personality disorder symptoms may be associated with processes that influence course and treatment responsiveness in common presentations such as adolescent deliberate self-harm. It is also possible that in the same individual, symptoms below diagnostic threshold from more than one disorder may each have prognostic significance. There are many more patients with symptoms below the threshold for diagnosis than those who meet criteria for disorder.

Utility of the personality disorder concept in childhood and adolescence

It is commonly assumed that personality disorders can only be identified from the age of 18, although DSM-5 requires this only for ASPD and ICD 10 refers to “adult” personality disorders without specifying an age. Equally DSM-5 and ICD 10 require that the pattern of behaviors contributing to personality disorder must have started at least by adolescence, begging the question as to what that pattern is if it does not yet amount to personality disorder. How good is the case for applying the concept of personality disorder in adolescence or even in childhood? Clearly, given the probable heterogeneity of the personality disorders, it is unlikely that there will be one answer to this question. Therefore the advantages and disadvantages will be considered in general, and specific examples tested against these.

Perhaps the most radical step would be to apply the concept of personality disorder to childhood disorders, particularly ODD and CD. Angold and Costello (2001) concluded that early onset antisocial behaviors in children satisfy all the DSM requirements for personality disorders. Childhood oppositional and conduct problems are associated with persistently poor peer relationships and broader difficulties (Vitaro *et al.*, 2000). Adult antisocial outcomes are most common in children with multiple and diverse oppositional, social, and educational difficulties (Stattin & Magnusson, 1996).

On the other hand, the use of the personality disorder designation could introduce the limitations of the adult concept into childhood. Crucially it might reduce our scope to investigate the links between different types of dysfunction. For example, Vitaro *et al.* (2000) found that, in boys, although having a best friend who was deviant age 10 predicted delinquency at age 14, this was much less the case among those with warm relationships with their parents. Such specific mechanisms could not be investigated within a personality disorder framework if having poor peer relationships was simply one of a number of items within a childhood ASPD. Similarly, notwithstanding the strong association of CD and ADHD and evidence that ADHD in the presence of CD increases the likelihood of persistence (Loeber *et al.*, 1995), important genetic and neuropsychological differences would not have been identified if they had been included in a hyperactivity-conduct personality disorder.

Is there a case for applying adult personality disorder criteria in adolescence? Studies of hospital patients, mainly of BPD, have suggested that adolescent personality disorders may be less distinct and less stable than adult disorders, but the profile of symptoms is largely similar (Becker *et al.*, 2002). Moreover there is evidence that a diagnosis of personality disorder is clinically relevant. For example, in a study of adolescent outpatients, the diagnosis of a personality disorder was associated with poorer treatment outcomes (Strandholm *et al.*, 2013). Stability is no less during adolescence, and from adolescence to adult life, than it is in adult life (Cohen *et al.*, 2005). Correlation coefficients of

between 0.5 and 0.7 are commonly reported between adolescent and adult measures and over periods of up to 10 years. BPD symptoms in adolescence predict multiple outcomes in adult life (Cohen *et al.*, 2005; Stepp, 2012; Winograd *et al.*, 2008). Equally there can be informative developmental sequences involving personality disorder symptoms. Hamigami *et al.* (2000) showed that there were reciprocal effects of narcissistic and borderline symptoms on each other from early adolescence into the mid-20s. Borderline symptoms predicted increasing narcissistic symptoms over time, but narcissistic symptoms predicted lower borderline symptoms! This may indicate that the appearance of borderline symptoms in early adolescence reflects substantial underlying pathology, whereas early narcissistic symptoms may be more developmentally benign. Later narcissistic symptoms, by contrast, may also reflect more problematic functioning, perhaps particularly when associated with borderline features.

Specific personality disorders

Antisocial personality disorder

Repeated criminality is central to ASPD, but ASPD involves diverse and pervasive difficulties. These include impulsivity, irritability, risk taking, lying, lack of remorse, and failures in adult social roles such as in work or family relationships. ASPD is more commonly found in males than females. The general population prevalence is between 2% and 3%, and it has been identified in around 60% of male prisoners (Moran, 1999). Adult symptoms of ASPD are almost always preceded by childhood disruptive behavior problems. Psychopathic disorder is identified in a smaller group of antisocial adults, most of whom have ASPD, and is associated with distinctive patterns of offending and neurobiological correlates. In childhood there appears to be a subset of antisocial children with “callous unemotional” traits with distinctive genetic and neurobiological contributions that may be the precursors of adult psychopathic disorder (Viding *et al.*, 2005; Blair *et al.*, 2006; Frick & White, 2008). The links between childhood disruptive behavior problems, callous unemotional traits, ASPD, and psychopathic disorder are described in Chapter 68.

Antisocial personality disorder in adolescence

Most developmental studies of ASPD have been influenced by the DSM model that ODD, typically seen in childhood, creates the vulnerability for CD, commonly identified during adolescence, which in turn predisposes to ASPD in adult life (Burke *et al.*, 2010). The associations over time among these three disorders have been widely replicated. However, as a consequence of this approach, studies comparing each of the three diagnoses at the same time point are lacking. We therefore do not know whether anything is gained by using the diagnosis, for example in adolescence. Some items, such as lying, aggressive behaviors and law breaking overlap with DSM CD, while others such as irritability overlap with DSM ODD. The new DSM-5 specifier for

CD, of whether or not the individual shows limited empathy and concern for the feelings or well-being of others, has some overlap with the ASPD item of “lack of remorse”. However ASPD also includes impulsivity, disregard for safety of self or others, and repeated failure to sustain work behavior or honor financial obligations, which are not found in either CD or ODD. Two of these three items refer to difficulties in social interactions, in common with conceptualisations of personality disorder that include social role dysfunction as well as deviant behaviors.

Neurobiological correlates have been examined in structural and functional imaging studies. A meta-analysis of studies published up to 2007 (Yang & Raine, 2009) found substantial heterogeneity in the way antisocial and control groups were identified, and so the results cannot be assumed to apply specifically to ASPD. Nevertheless, analyses using data from 43 studies showed significantly altered structure and reduced function in some regions of the prefrontal cortex in antisocial individuals. Imaging studies focusing on the psychopathic subgroup of ASPD have implicated impairments in the amygdala which is involved in processing other people’s emotional expressions and the formation of stimulus-reinforcement associations, and the ventro-medial prefrontal cortex which influences decision making linked to the representation of reinforcement expectancies (Blair, 2008). However there have also been substantial differences in findings across studies, many attributable to variations in methodology (Koenigs *et al.*, 2010).

Borderline personality disorder

BPD involves pervasive instability of interpersonal relationships, self-image, affects, and control over impulses. For example, problems can include frantic efforts to avoid real or imagined abandonment, unstable and intense interpersonal relationships, unstable self-image, impulsivity, recurrent suicidal behavior, affective instability, chronic feelings of emptiness, inappropriate intense anger, and transient paranoid or dissociative symptoms. In contrast to ASPD, BPD is more commonly diagnosed in females than males in clinical settings. Prevalence estimates for BPD have varied substantially, between 0.5% and 5.9%, in general population studies; however, the rate is likely to be between 1% and 2% (Torgersen *et al.*, 2001; Coid *et al.*, 2006; Lenzenweger *et al.*, 2007). Several epidemiological studies have not found a higher rate of BPD in women, suggesting that males with borderline problems seek treatment less than females.

Many individuals have both antisocial and borderline features, and some traits such as impulsivity are core to both disorders (Paris, 2005). It is possible that there is a common origin in early onset disruptive behavior problems, with a divergence in adolescence or early adult life. This is supported by prospective studies examining borderline symptoms in early adolescence (Belsky *et al.*, 2012; Stepp *et al.*, 2012). Prospective studies have not so far revealed whether the distinctive borderline symptoms are seen in childhood. Retrospective studies suggest that, as children, adults with BPD may have had difficulties with

separating from emotionally important people and high mood reactivity (Reich & Zanarini, 2001) and that many started to self-harm before the age of 12 (Zanarini *et al.*, 2006).

Many theories of the origins of BPD have proposed a central role for maltreatment, and in particular, experiences of sexual abuse in childhood. If this were the case, there would be a particularly important preventative role for child care and mental health professionals. BPD in adults is associated with higher rates of recalled child sexual abuse compared to non psychiatric controls, but so are many other psychiatric disorders (see Chapter 30), and specificity to BPD has not been conclusively demonstrated (Fossati *et al.* 1999). It is possible that specific types of sexual abuse show more specificity. In a comparison of borderline patients and those with other personality disorder, based on retrospective accounts, those in the borderline group were more likely to have been abused by a male non-caretaker, to have experienced denial of their thoughts and feelings by a male caretaker and to have experienced inconsistent treatment by a female caretaker (Zanarini *et al.*, 2000). As we saw earlier, in a general population study by Cohen and colleagues, particular patterns of mother–child interaction were associated with subsequent BPD (Bezirgianian *et al.*, 1993). There may also be specificities between type of maltreatment and features of BPD. For example, individuals with BPD also report more dissociative experiences (Jones *et al.*, 1999) and these may be associated specifically with sexual abuse by a caretaker (Zanarini *et al.*, 2000). Apparent environmental effects can arise from common genetic influences on parents and children. In a longitudinal twin study, genetic influences on BPD symptoms at age 12 were identified, and so were environmental effects of harsh treatment earlier in childhood (Belsky *et al.*, 2012). By contrast, in a twin study of young adults, child maltreatment was associated with BPD symptoms, but the association was fully accounted for common genetic influences (Bornovalova *et al.*, 2013).

Theories regarding mechanisms in BPD have focused on impulsivity (Paris, 2005), emotion dysregulation (Putnam & Silk, 2005), unresolved or insecure attachment (Levy, 2005) and failure of mentalization (Bateman & Fonagy, 2004). Some of the features of BPD, including suicide attempts and self-mutilation, may reflect a more general trait of impulsivity. Impulsive spectrum disorders, such as ASPD and substance misuse, are elevated in the first degree relatives of borderline patients (White *et al.*, 2002), and levels of impulsivity predict clinical outcomes in BPD (Links *et al.*, 1999). However, disorders other than BPD are also characterised by impulsivity, notably ASPD, and although there is substantial overlap between the disorders, there are important differences.

Emotion dysregulation is likely to be one of the keys to the difference between BPD and ASPD. “The inability to sustain positive affect coupled with the pervasive and unrelenting distress as experienced by patients with BPD can become a veritable prison to those with the disorder and often as well to those who attempt to treat the individual with BPD” (Putnam & Silk, 2005, p. 900). Borderline individuals commonly have a low

threshold for reacting to events, or to anticipated events (such as abandonment), with intense negative emotion. According to Linehan (1993) BPD arises from an interaction between temperamental emotional reactivity and an “invalidating” environment in which the child’s communication about inner emotional experience is regarded as reflecting an inaccurate perception of self and others. One of the major consequences of this response is thought to be that children raised in these environments do not learn to identify emotional states accurately, nor do they learn to regulate affect, as it is more often than not denied. In addition, invalidating environments also intermittently reinforce escalations of emotional displays. This results in two opposing responses to affect being shaped. The first is the inhibition or denial of emotional states, and the second is an extreme response, which often appears to be inappropriate to the level of the stimulus that elicited it. This hypothesis has not so far been tested in prospective studies.

Instability of family and romantic relationships characterised by highly intense interactions, fear of abandonment and emotionally charged breakdown are also common in individuals with BPD. Several studies have linked this to disturbances of attachment (Levy, 2005), although very few have tested whether attachment difficulties are associated specifically with borderline, as opposed to other personality disorders. Bateman and Fonagy (2004) argue that borderline individuals have an impoverished model of their own and others’ mental function (mentalization), “Their schematic, rigid and at times extreme ideas about their own and others” states of mind make them vulnerable to powerful emotional storms and apparently impulsive actions, and create profound problems of behavioral and affect regulation’ (Bateman & Fonagy, 2004, p. 2) They also argue that these limitations in mentalization are seen particularly in relation to attachment relationships, thus leading to particular difficulties in close relationships.

BPD is associated with difficulties in a wide range of relationships in personal and work life, including problems in maintaining distinct boundaries between different relationship domains. A key feature of this “domain disorganisation” (Hill *et al.*, 2008) is the presence of features of intimate relationships in social domains where these are not readily accommodated. For example, exclusivity is generally found only in romantic relationships. In a short-term longitudinal study from childhood into early adolescence, “friendship exclusivity” was a strong independent predictor of borderline symptoms (Crick *et al.*, 2005). Domain disorganisation may contribute to BPD in the presence of increased emotional reactivity. In a study of psychiatric outpatients the combination of domain disorganisation and temperamental anger proneness was associated with BPD (Morse *et al.*, 2009).

Repeated self-injury, cutting, burning, or hitting, is frequently observed in individuals with severe personality disorders, and is one of the diagnostic items for BPD. It is a serious and puzzling phenomenon. There is a wide range of theories concerning the motivation for self-injury, and themes that are common to most

of them are of regulation of emotions, communication, and social reinforcement (Kemperman *et al.*, 1997). Linehan (1993) has proposed that self-injury directly relieves painful emotions and is reinforced by the attention and care given by others. Several studies have supported the role of self-injury in reducing painful affect although most have used retrospective measures with samples that in different ways were unrepresentative. In the prospective Collaborative Longitudinal Personality Disorders Study of 290 patients meeting DSM criteria for BPD, all of female gender, severity of dysphoric cognitions (mostly overvalued ideas), severity of dissociative symptoms, major depression, history of childhood sexual abuse and sexual assaults as an adult predicted self-harm over a 10-year follow-up period (Zanarini *et al.*, 2011).

BPD is also associated with elevated environmental stresses or traumas in adult life that in turn contribute to persistence of problems. Over a 10-year follow-up period of patients in the Collaborative Longitudinal Personality Disorders Study, BPD was associated with significantly more total negative life events than other personality disorders, or major depressive disorder (Pagano *et al.*, 2004). Negative events, especially interpersonal events, predicted decreased psychosocial functioning over time. In the same study BPD predicted, more strongly than other personality disorders, verbal, emotional, physical, and sexual abuse, and adult experiences of abuse were associated with failure to remit from BPD (Zanarini *et al.*, 2005).

Studies of the neurobiology of BPD have focused on impaired behavioral control in the context of intense negative emotions. The “frontolimbic disconnectivity” model of BPD suggests that emotional dysregulation in BPD patients is caused by prefrontal deficits or hyperactivity of the limbic system, or a combination of both. This conceptualization of frontolimbic dysfunction in BPD has resulted in a growing number of imaging studies using structural and functional methods (Maier-Hein *et al.*, 2014) that have provided some support for the hypothesis. For example, Silbersweig *et al.* (2007) compared 14 BPD patients with 12 controls on an executive function task using negative, neutral, and positive stimuli administered during functional magnetic resonance imaging (fMRI). The BPD patients showed decreased ventromedial prefrontal cortex activity compared to controls specifically when inhibiting responses in the presence of negative stimuli. Promising though this work is, it has so far been limited to small-scale cross-sectional studies with nonclinical control groups, and so the differences may not be specific to BPD.

Borderline personality disorder in adolescence

Many of the studies of personality disorder in adolescence have focused on BPD. A substantial proportion of adolescent psychiatric in-patients in the USA and the UK can be diagnosed with the disorder using adult criteria. It resembles the adult diagnosis in that there is a strong association with episodic disorders, particularly depression. In adolescents, the BPD diagnosis picks out a group who, compared with other adolescent psychiatric

patients, have experienced high levels of maternal neglect and rejection, grossly inappropriate parental behavior and a number of parental surrogates and sexual abuse (Ludolph *et al.*, 1990) and higher levels of angry, irritable interactions in the family (James *et al.*, 1996). Associations of inconsistent and intrusive parenting with the emergence of BPD were found in the longitudinal study of a general population sample (Bezirgianian *et al.*, 1993) referred to earlier. BPD identified in adolescence also has prognostic value (Stepp, 2012). In a large community sample, higher levels of BPD symptoms during adolescence predicted less productive adult role functioning over 20 years, including poor academic and occupational achievements. BPD symptoms also predicted poor social and relationship functioning, including lack of social support and less involvement in romantic relationships well into adulthood (Winograd *et al.*, 2008). In a study of psychiatric patients, mean age = 15.47, BPD (omitting the suicidality criterion) predicted suicidality and repeat self-harm over and above their association with DSM Major Depressive Disorder (Sharp *et al.*, 2012). There is limited evidence from studies of BPD adolescents of white matter differences from clinical and healthy controls consistent with the evidence from adults based on the frontolimbic disconnectivity model (Maier-Hein *et al.*, 2014).

Schizotypal personality disorder

The general concept of SPD is that of a pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood. It is likely that the concept of a spectrum of schizophrenic disorders, including SPD, applies in the preadult years, as well as later. However, there has been only a small number of attempts to apply the criteria in childhood. One study suggested an overlap with pervasive developmental disorders, although not autism as such (Nagy & Szatmari, 1986); another suggested a course similar to that of schizophrenia arising in childhood (Asarnow & Ben-Meir, 1988); and a third suggested that there was a pattern of communication deficits similar to, but milder than, those found in schizophrenia (Caplin & Guthrie, 1992). Olin *et al.* (1997) gathered prospective questionnaire data from teachers on 15-years-olds who subsequently developed SPD. Compared to a range of other groups at varying levels of risk for psychiatric disorder other than schizophrenia, the schizotypal individuals as adolescents had been more passive and unengaged and more hypersensitive to criticism. In a small follow-up study over 3 years of young adolescents diagnosed with SPD there was substantial stability of the disorder and also a substantial minority developed psychotic disorders (Asarnow, 2005).

Schizoid personality disorder

The usual concept of schizoid personality disorder is of a pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal

settings (DSM-IV, American Psychiatric Association, 2000). Thus, ICD-10 criteria (World Health Organization, 1996) include a lack of pleasure in activities, emotional coldness, apparent indifference to praise, or criticism, a limited capacity to express either positive or negative emotions, lack of close friends, a preference for solitary activities, a marked insensitivity to prevailing social norms and an excessive preoccupation with fantasy and introspection. The literature on the syndrome is almost confined to adults (Esterberg *et al.*, 2010). However, from the 1970s, Wolff pressed the case for the application of the diagnosis in childhood (Wolff & Barlow, 1979). Unfortunately for comparative purposes, her criteria differ in several key respects from those generally applied with adults. Thus, she specified increased sensitivity and paranoid ideas, whereas ICD-10 and DSM-IV indicate marked insensitivity, and she included an unusual odd style of communicating which would ordinarily be part of schizotypal, not schizoid, personality disorders (Wolff & Chick, 1980; Wolff, 1991a, b). The initial findings in childhood suggested some similarities with autism (Wolff & Barlow, 1979) and the follow-up showed substantial continuity with SPD in adult life (Wolff *et al.*, 1991). However, a study of psychophysiological responses of adults who in childhood met Wolff's criteria for schizoid disorder failed to find abnormalities previously documented in the relatives of schizophrenic patients and adults with SPD (Blackwood *et al.*, 1994).

The application of personality disorders research in clinical practice

Assessment

Two contrasting conclusions can be drawn regarding personality disorder assessment in clinical practice with adolescents. First, identifying personality disorder features is important because it highlights phenomena not covered by episodic disorders. Second, in contrast, many issues remain unresolved in the assessment of these features. For example, some non-episodic disorders, such as ASD and behavioral disorders, are not generally considered as personality disorders.

In view of the lack of studies comparing the utility of the ASPD, CD and ODD diagnoses in adolescence, we do not know whether making the ASPD diagnosis in adolescence has implications for prognosis or has advantages in formulating treatment. The alternative diagnoses to be considered for a young person presenting with repeat offending or violence will generally be the same, irrespective of whether the problem is formulated in terms of ASPD or of CD. In particular, previously undetected ADHD, which carries a greatly increased risk for CD (see Chapter 55), may make a major contribution to the presenting problems, and provides a clear treatment focus. By drawing attention to a broader set of problems than either conduct or ODD, particularly social impairment, ASPD may highlight additional key targets for intervention and indices of change. However, it is important when offending is accompanied by problems in social

and educational performance, to assess for autistic spectrum disorders which are over represented among young offenders (Siponmaa *et al.*, 2001). This will require detailed enquiry into the characteristics of the social impairment, together with a developmental history and possibly administration of a standardized ASD assessment (see Chapter 51).

Where the presenting problems occur in the context of an identifiable current episodic disorder, such as depression or an anxiety disorder, enquiry into functioning prior to the onset is essential. Key features that point toward borderline difficulties include persistent problems in multiple domains of interpersonal functioning, rapid and marked changes of mood, and unpredictable impulsive behaviors. Difficulties in maintaining the demarcations between social domains referred to earlier as domain disorganization are often evident in intense personalized interactions in settings where these are not readily accommodated, such as school or college, and in intimate relationships established rapidly and without adequate time to evaluate the quality of partners. This in turn contributes to relationship breakdown and lack of social support, increasing the risk of adverse life events that in turn contribute to further impairment. It is common for young people with borderline problems to have had contact with multiple agencies and for there to be several professionals involved, each with strong and conflicting impressions of the young person. There is no established method for making dimensional assessments of borderline PD. Studies described earlier showing the advantages of a dimensional approach used DSM PD symptom counts. However, a comprehensive assessment often requires enquiry along several dimensions. In particular, in the light of the persistence of social dysfunction in adult BPD, detailed accounts of the degree of impairment in interpersonal functioning in school, quality of friendships and wider peer relationships, provide an indication of the extent of the dysfunction and identify targets for intervention.

Affective instability and repeat self-harm, commonly seen in adolescent patients, may reflect borderline disorder or dysfunction; however, it is important to consider other possible diagnoses with very different implications. Bipolar disorder, especially Bipolar II characterized by relatively short periods of elation together with depression, may look very similar. In principle there are substantial differences in that, compared with bipolar disorder, affects are more unstable and triggered by interpersonal events in BPD, and there are characteristic interpersonal problems in BPD not seen in bipolar disorder (Zimmerman *et al.*, 2013). However where bipolar symptoms have persisted for some time they may have impacted on interpersonal functioning, making the distinction difficult. Recent evidence for pathways from childhood disruptive behavior problems to adolescent borderline symptoms (Belsky *et al.*, 2012; Stepp *et al.*, 2012) would suggest that the presence of behavior problems before adolescence may support the diagnosis of BPD. However, the evidence is not strong enough to conclude that the absence of childhood problems would rule

it out. Crucially, in adults there is an elevated co-occurrence of bipolar disorder in BPD, compared to other personality disorders (Gunderson *et al.*, 2006), so the presence of both may need to be considered. Clinical experience suggests, although relevant research evidence is lacking, that adolescent girls with undetected autistic spectrum disorder may present with impulsive behaviors, including self-harm, in the context of social difficulties with peers that may be interpreted as markers for borderline problems. A developmental history together with clinical and standardized assessments of current functioning will generally clarify the picture,

Whatever the merits for clinicians of using the concept of personality disorder, either as a category or dimension, there is some concern over making explicit reference to it when explaining the nature of their problems to young people and their families. The label, it is argued, runs the risk of stigmatising and of creating therapeutic pessimism. Equally, patients and their families are entitled to an explanation of their problems and in some instances the personality disorder concept may be helpful to that process. In that case, the explanation needs also to reflect the uncertainties regarding the nature of the personality disorders reviewed in this chapter. Perhaps surprisingly, given its importance, systematic research into this question is lacking, both for adults and adolescents.

Treatment

Psychodynamic and cognitive-behavioral treatments have been advocated for treating ASPD in adults, however there has only been one RCT, with a sample size of 39, which found no effect of cognitive behavioral treatment (Davidson *et al.*, 2009). No well-designed studies of pharmacotherapy in ASPD have been conducted. Studies of treatments for adolescent offenders are relevant but do not yet address whether they are effective for the pervasive problems identified by the disorder. There is good evidence, for example, that multisystemic therapy is effective in improving outcomes for juvenile offenders (see Chapters 49 and 50), but less clear evidence for adolescents with CDs (Sundell *et al.*, 2008). Early intervention to prevent disruptive behavior problems, and hence reduce risk for ASPD, would seem to be the most promising approach to a disorder that seems to be so intractable by adolescence. Promising findings have been reported from randomised controlled trials of prenatal and early postnatal nurse visiting, and parenting and school-based interventions for young children. Effects on cognitive skills, school attainment, earning capacity, health, and mental health, rates of delinquency and crime have been reported (NCCMH, 2010). However most studies have reported on multiple outcomes, with effects on some but not others, and we do not yet know whether early intervention can reduce the persistent and pervasive problems characteristic of ASPD.

In relation to BPD in adults, Bateman and Fonagy (2004) have summarized the principal features of treatments for which there is some evidence of effectiveness. The approach is active and structured with clear focus, in the context of a strong

relationship between therapist and patient over a substantial period of time. This is consistent with accumulating evidence that structured, manualized psychotherapeutic treatments delivered by trained clinicians working within a team are superior to treatment as usual for adults with BPD (McMain *et al.*, 2012). Treatment superiority has been shown in randomised controlled trials in adults for dialectical behavior therapy (DBT; Linehan *et al.*, 2006), out-patient mentalization-based therapy (Bateman & Fonagy, 2009) and cognitive analytic therapy (Clarke *et al.*, 2013) (see Chapters 38 and 40). Mentalization-based partial hospitalization showed substantial superiority to treatment as usual over an 8-year follow-up period (Bateman & Fonagy, 2008). McMain *et al.* (2012) found no differences in a range of outcomes between DBT and an alternative manualized psychotherapeutic approach, implying that treatment effects arise from the general characteristics of the intervention rather than specific therapeutic processes. By contrast, Bateman and Fonagy showed medium effect size (Cohen's *d* around 0.60) reductions in suicidal behaviors, self-harm, and hospital admissions for mentalization in a comparison with an alternative manualized treatment programme (Bateman & Fonagy, 2009). A systematic review of psychological treatment trials for BPD up to 2010 concluded, "Overall, the findings support a substantial role for psychotherapy in the treatment of people with BPD but clearly indicate a need for replicatory studies" (Stoffers *et al.*, 2012).

DBT is increasingly being used as an approach with suicidal adolescents, many of whom are likely to have BPD symptoms (Katz *et al.*, 2004). The "dialectic" refers to helping the adolescent to change what needs to be changed, while accepting what is a valid response to circumstances (Hill *et al.*, 2006). Treatment is delivered by a team, and has several elements. "Capability enhancement" aims to increase the adolescents' basic capabilities of affect regulation, distress tolerance, and interpersonal skills. This function is most often delivered by a skills-training group. "Motivational enhancement" involves assisting adolescents to apply their new-found skills to their own life problems, in particular attending to thoughts, emotions, or reinforcement contingencies (such as repeated attendance at hospital for self-harm) that interfere with the implementation of skilful behavior. This function is most commonly delivered via individual psychotherapy. Explicit coaching in the application of problem-solutions to the adolescent's real world situations is designed to increase generalization of skills learned in the programme. This may be delivered by between-session skills coaching, by telephone, by case management or by training family members in the same skills that the adolescents are learning. Considerable attention is also paid to supervision and support of therapists and to the family and wider environment of the adolescent, including social services and education. DBT has shown promise in the treatment of borderline problems in adolescents (James *et al.*, 2007, MacPherson *et al.*, 2013), and support for its effectiveness has come from a randomized controlled trial of 77 adolescents with repeat self-harm and at least three BPD symptoms. Compared to enhanced treatment as usual DBT

was associated with lower levels of self-harm, suicidal ideation and depressive symptoms soon after completion of treatment (Mehlum *et al.*, 2014).

Studies have been conducted of tricyclic antidepressants, selective serotonin reuptake inhibitors, neuroleptics, and mood stabilizers in BPD (Lieb *et al.*, 2004; Leichsenring *et al.*, 2011). Most have shown some evidence of efficacy but only in small samples. Of the 16 studies reviewed by Lieb *et al.*, only two had a sample size of greater than 60, and in most cases they were substantially smaller. In one of the more promising studies, Soler *et al.* (2005) randomised 60 patients with BPD to placebo or to olanzapine together with DBT. In assessments after 4 months, the combined DBT plus drug group had lower affective symptoms and impulsivity/aggression than the DBT only group. Overall, in spite of some promising findings, there is a lack of sufficiently large randomised controlled trials with follow-up long enough to inform the treatment of this persistent disorder (Leichsenring *et al.*, 2011).

Conclusions

Much remains to be discovered regarding the forms of dysfunction that best characterize personality disorders. This will inform, and be informed by, increasing knowledge of childhood antecedents, developmental pathways, the interaction between individual and environmental processes, and basic psychopathological processes in personality disorders. For all its shortcomings, the concept of personality disorder has endured because it adds to our understanding of risk and psychopathology, and increasingly research in this area highlights individuals with distinctive treatment needs. Patterns of symptomatology resembling adult personality disorders are seen during adolescence and also indicate distinctive, and generally intensive, treatment needs.

Developmental risk for psychopathy

Essi Viding^{1,2} and Eamon McCrory¹

¹Faculty of Brain Sciences, University College London, UK

²Institute of Psychiatry, Psychology and Neuroscience, King's College London, UK

Introduction: characteristics and diagnosis of psychopathy

The origins of the current description of the psychopathy syndrome

The origins of the current description of the psychopathy syndrome can be traced back to the work of Cleckley (1941) and his book, *The Mask of Sanity*. Some of the key features of psychopathy recorded by Cleckley (1941) included: absence of nervousness, interpersonal charm, lack of shame, impoverished affect, and poorly motivated antisocial behavior. From the criteria delineated by Cleckley, and his own clinical impressions, Robert Hare developed the original psychopathy checklist (PCL) (Hare, 1980), a formalized tool for the assessment of psychopathy in incarcerated adults. On the basis of considerable empirical work, this has been revised, first in 1991, the Psychopathy Checklist—Revised (PCL-R) (Hare, 1991), and then again in 2003 (Hare, 2003). The first extension of the psychopathy concept to children was Bowlby's (1946) description of "affectionless psychopathy." It mirrored some of the key features introduced by Cleckley (such as lack of responsiveness to suffering of others), but lay forgotten for a long time until the extension of psychopathy construct to children was proposed again by Frick and colleagues (1994).

The current definitions of psychopathy in adults comprise both ratings of emotional dysfunction as well as ratings of overt antisocial behavior. The emotional dysfunction definition involves reduced guilt and empathy as well as reduced attachment to significant others. In children, these features have been variously termed "callous-unemotional" (CU) traits "psychopathic traits," and most recently in DSM-5, "limited prosocial emotions." These terms are used interchangeably in this chapter. The majority of extant research has focused on children with these features in the context of conduct problems/conduct disorder (CD). Children with conduct problems may or may not present with the specific form of reduced emotional

responsiveness characteristic of CU traits (Frick & Viding, 2009). Introduction of the "lack of prosocial emotions" specifier to the DSM-5 reflects the accumulating evidence base pointing to etiological and neurocognitive differences between children with CD who have high versus low levels of CU traits (see e.g., Viding & McCrory, 2012), with the former group thought to be at risk for developing psychopathy in adulthood (Lynam *et al.*, 2007).

Chapter overview

This chapter will first outline current practice in the assessment of traits in children that have been associated with psychopathy. We will also overview what is known about prevalence, longitudinal outcomes, and risk factors, as well as current accounts of the pathophysiology of children with psychopathic features. Finally, treatment considerations will be discussed in the light of the existing evidence base.

Assessment

Following the adult PCL-R, tools for the assessment of psychopathic traits in childhood and adolescence have also been developed. The Psychopathy Checklist: Youth Version (Forth *et al.*, 2003; Kosson *et al.*, 2002) is widely used in juvenile justice settings, particularly in North America. The PCL-YV is scored on the basis of an extensive file review and a semistructured interview. Commonly used measures for community samples of children and youth include the Antisocial Process Screening Device (APSD) (Frick & Hare, 2001), which charts CU, narcissistic, and impulsive traits; and the Inventory of Callous-Unemotional (ICU) traits (Frick, 2003), which was specifically developed to more thoroughly assess CU traits in children. Both measures take the format of parent, teacher, or child-rated questionnaires. The inter-rater reliability for these measures is comparable with other instruments assessing

psychopathology (e.g., Frick & Hare, 2001; Frick *et al.*, 2003b; Roose *et al.*, 2010). For children, moderate to strong stability of the CU traits across childhood and adolescence has been demonstrated in a number of studies (e.g., Frick *et al.*, 2003b; Obradovic *et al.*, 2007). Obradovic and colleagues (2007) also reported that CU traits from childhood to adolescence had longitudinal invariance, that is, were represented by similar behavioral indices at different ages. To date, CU traits have not been routinely assessed during psychiatric assessment of CD. However, the DSM-5 now includes a “limited prosocial emotions” specifier (essentially CD with CU traits), which is discussed below.

DSM-5 conduct disorder with limited prosocial emotions

The recent DSM-5 has introduced a specifier to delineate a group of children with CD who show “limited prosocial emotions.” The indicators of this specifier are those that have been labeled CU traits in research. The specifier includes four symptoms:

- 1 “Lack of remorse or guilt”
- 2 “Callous lack of empathy”
- 3 “Shallow or deficient affect”
- 4 “Unconcern about performance at school or work.”

Children have to qualify for CD diagnosis and present with at least two symptoms from the specifier for at least 12 months, as indicated by two independent raters.

It may be helpful, for example, for the clinician to take time to explore age-appropriate situations that may have elicited guilt or empathy. These could include asking about feelings when witnessing younger children in distress, thoughts about hurting someone else, deliberate cruelty toward others, and discussing feelings of remorse. There is also preliminary evidence that cruelty toward animals, which may arise in CD in general, may be particularly prevalent for those children with high CU traits (Dadds *et al.*, 2006; Vizard *et al.*, 2007). The administration of the ICU to multiple informants (self-, teacher-, and carer-ratings) can be a helpful adjunct to the material garnered from case files and clinical interview with the young person and carer (White *et al.*, 2009; Kimonis *et al.*, 2013). Naturally, clinical judgment needs to be deployed when discussing a diagnosis of CD with “limited prosocial emotions” sensitively with parents/carers and the young person themselves.

Co-occurrence with other disorders

Attention deficit hyperactivity disorder (ADHD)

Considerable work has demonstrated that CD and attention deficit hyperactivity disorder (ADHD) often co-occur, and that individuals with CD and high CU traits also have high levels of ADHD symptoms (e.g., Taylor *et al.*, 1986; Hinshaw, 1987; Lynam, 1996; Barry *et al.*, 2000; Colledge & Blair, 2001; Fontaine *et al.*, 2011). Recent data suggest that impulsivity in ADHD and CD are likely to be driven by distinct neurocognitive vulnerabilities (Rubia, 2011). However, it remains unclear whether ADHD symptoms seen in the context of CD with high CU traits can be

considered equivalent to ADHD that occurs in the absence of these traits, or whether it should be considered as a behavioral phenocopy with a divergent neurocognitive signature (Blair *et al.*, 2005). What we do know, is that a key distinguishing characteristic that sets apart children with ADHD and CD with CU traits clinically, is the presence versus absence of callous, remorseless, and unempathic behaviors.

Autism spectrum disorders (ASDs)

Autism spectrum disorders (ASDs) are associated with problems in socially appropriate behavior (see Chapter 51), which have led people to question the degree to which these disorders may be related to CU traits. However, the nature of the social impairment appears very different between the two populations (Jones *et al.*, 2010; Schwenck *et al.*, 2012). Individuals with ASD, as a group, tend to show impairment in Theory of Mind, the ability to represent the mental states of others (Baron-Cohen *et al.*, 1985; Frith & Happe, 2005; Jones *et al.*, 2010; Schwenck *et al.*, 2012). Children with CU traits do not (Jones *et al.*, 2010; Schwenck *et al.*, 2012). Instead children with CU traits have difficulties in processing other people’s distress (fear and sadness) and do not report appropriate concern for other people’s suffering (Blair *et al.*, 2001; Jones *et al.*, 2010; Schwenck *et al.*, 2012), that is, they are poor at feeling for others, while being capable of representing mental states. Individuals with ASD, while potentially showing a global impairment in processing emotions, appear to find others’ distress aversive (Adolphs *et al.*, 2001; Jones *et al.*, 2010; Rogers *et al.*, 2006; Schwenck *et al.*, 2012). To date there are a few reports of co-morbid CU traits/psychopathy and ASD (Fine *et al.*, 2001; Rogers *et al.*, 2006), but twin research indicates that the etiological (both genetic and environmental) factors contributing to each symptom domain are mostly independent (Jones *et al.*, 2009a). As pointed out by Rutter (2005), unlike for psychopathy, the impaired socio-emotional responsiveness found in ASD does not seem to be typically linked to increased risk for antisocial behavior compared to the general population. In support of this, Hippler and Klicpera (2003), in their study of 177 cases originally diagnosed by Asperger, found no raised incidence of criminal offences compared with general population rates in individuals with ASD. In contrast, Frick and colleagues have demonstrated that elevated levels of CU traits predict increased antisocial behavior at a later time point, even in children who do not start off as having clinically elevated rates of antisocial behavior (Frick *et al.*, 2005). It thus appears that although both children with CU traits and children with ASD can appear to behave in an emotionally blunted manner, there are likely to be different roots to their emotional problems that also explain the lack of increased risk for antisocial behavior in people with ASD.

Anxiety and mood disorders

Psychopathy has been traditionally considered to be marked by reduced anxiety levels (Cleckley, 1941; Hare, 1970;

Lykken, 1957). In general, psychopathic traits are associated with reduced levels of anxiety (e.g., Patrick, 1994; Frick *et al.*, 1999; Verona *et al.*, 2001). However, recent research suggests that some children present with concurrent psychopathic traits and anxiety (Kahn *et al.*, 2013; Fanti *et al.*, 2013). These children differ from those with psychopathic traits and non-elevated anxiety in a number of other respects. For example, they are more likely to have experienced childhood maltreatment and show greater attentional bias to emotional stimuli than children with psychopathic traits and low levels of anxiety (e.g., Kimonis *et al.*, 2012). Such differences are likely to be clinically relevant and require further research.

Differential diagnosis

While making a diagnosis of CD should be relatively straightforward, it is possible that behavioral symptoms associated with other disorders may be misconstrued as antisocial (e.g., irritability in depression, certain patterns of hyperactive behavior). In relation to CD with CU traits particular attention should be given to behaviors that may appear unempathic. Children with ASD and social communication disorder may also have difficulties in displaying an appropriate empathic response but as noted above, these difficulties are thought to stem from theory of mind (i.e., mentalizing) impairments rather than from deficits in their basic response to other people's emotions. As a result these children also have a host of other features indicating broader deficits in social interaction and communication not evident in children with CD and CU traits.

Summary—assessment

A number of standard measures, both questionnaires and interview/file ratings, have been developed to reliably assess CU features in children and adolescents, in research, forensic and clinical settings. The recent DSM-5 has introduced a specifier to delineate a group of children with CD with “limited prosocial emotions,” which can be regarded as largely analogous to the presence of CU traits as conceptualized in previous research. An established body of work has demonstrated that children with CD often present with symptoms of other disorders, such as ADHD and anxiety. Because an official clinical diagnosis of CD with CU traits (or CU) has not existed to date, we know relatively little about frequency of co-occurring disorders in these children. The existing evidence base suggests that elevated levels of CU traits can co-occur with symptoms of other disorders. For example, some children present with an atypical pattern of CU traits and anxiety symptoms; such a presentation may alert a clinician to a possible history of maltreatment. Furthermore, a differential diagnosis of other disorders of social impairment (e.g., ASD) is important for the clinician to consider during assessment.

Epidemiology and longitudinal outcomes

Prevalence

Prevalence estimates for CD vary across studies. A recent review provided a pooled prevalence estimate for CD, across a large number of studies, as 3.2% (Canino *et al.*, 2010). Only a few studies to date have estimated the prevalence of CD utilizing the “limited prosocial emotions” (CU) specifier. These studies indicate that 20–50% of children with CD also present with high levels of CU features (Kahn *et al.*, 2012; Pardini *et al.*, 2012). This points to a tentative prevalence level of 0.75–1.5% of children qualifying for CD with CU specifier. This prevalence rate is comparable to that estimated for adult criminal psychopathy (Blair *et al.*, 2005). Epidemiological as well as large community studies also indicate that CU traits can occur with nonclinical levels of CD symptoms (e.g., Rowe *et al.*, 2010; Barker *et al.*, 2011; Fanti, 2013), although it is not currently possible to provide precise prevalence estimates for this presentation as none of the studies adopted symptom count criteria for defining the groups. These studies also indicate that children with CU traits and nonclinical levels of CD symptoms nonetheless often present with elevated levels of conduct problems and other psychological problems. More research is required to understand the clinical significance of CU traits that occur without clinical levels of CD symptoms and how children with such a presentation progress across development.

CU traits in boys and girls

The DSM-5 specifier identifies girls who exhibit a similar profile (low anxiety, more severe aggression and psychosocial impairment) to boys with CD and high levels of CU traits. CD with high levels of CU traits, as well as high levels of CU traits (without clinical levels of CD) are more prevalent in boys than in girls (where available, data indicate that these presentations are three to five times as common in boys than in girls; e.g., Fontaine *et al.*, 2010; Fanti, 2013) and may have a different etiology in girls (Fontaine *et al.*, 2010).

Cultural factors

CU trait measurement and its construct validity have been assessed in several Western countries to date and the existing studies report remarkably similar findings (e.g., Essau *et al.*, 2006; Kimonis *et al.*, 2008; Fanti *et al.*, 2009; Ezpeleta *et al.*, 2013). However, research on how cultural factors may impact the expression of CU traits, both within and between countries, is needed.

CU traits as a risk indicator for behavioral/psychiatric maladjustment

Longitudinal research on large community samples suggests that CU traits predict antisocial and criminal/delinquent outcomes

(e.g., Frick *et al.*, 2003a; Fontaine *et al.*, 2010; McMahon *et al.*, 2010; Pardini & Fite, 2010). CU traits predict these outcomes over and above the prediction afforded by conduct problem severity alone (e.g., Frick *et al.*, 2003a; McMahon *et al.*, 2010; Pardini & Fite, 2010). Although the data with regard to internalizing problems (anxiety and depression symptoms) is less rich, some studies suggest that CU traits may be protective against development of internalizing problems (e.g., Pardini & Fite, 2010).

Prognostic value into adulthood

A long-term follow-up study measuring psychopathic traits at age 13 demonstrated that the construct showed moderate stability to age 24 years ($r = 0.32$), despite different informants and assessment instruments used across the two age periods (Lynam *et al.*, 2007). This 11-year correlation is equivalent to that typically seen when different informants use the same instrument at the same time-point to rate an individual's behavior on a construct. Another recent study included a measure of adult criminality and demonstrated that CU added predictive value over and above prior and concurrent conduct disturbance and ADHD symptoms (McMahon *et al.*, 2010).

Treatment outcomes

The moderating role of CU traits on treatment outcome has been assessed in a number of studies. These will be discussed in the treatment section of this chapter.

Summary—epidemiology and longitudinal outcomes

Epidemiological work is relatively sparse to date. This is no doubt to a large part due to the fact that CU traits have not been considered in clinical diagnostics and decision-making with children until very recently. As such, most of the large-scale epidemiological studies have not included standard CU trait assessment among their measures and prevalence estimates. Furthermore, the types of prevalence estimates that have been drawn from the current studies are often based on sophisticated longitudinal modeling (e.g., Rowe *et al.*, 2010), but are not easily translated to prevalence of CD with “limited prosocial emotions” as classified by DSM-5. Based on the available data, we estimate that CD with high levels of CU traits affects approximately 1% of children and is more common in boys than in girls. Additionally, there are groups of children with high levels of CU traits, but nonclinical levels of CD (see e.g., Rowe *et al.*, 2010; Kumsta *et al.*, 2012). Currently, very little is known about the neurocognitive presentation and long-term prognosis of these children. Cultural impact on the expression of CU also needs further investigation.

Longitudinal studies indicate that CU traits are predictive of persistent antisocial outcomes, including psychopathy in adulthood. CU traits add to the prediction of these outcomes, over

and above the prediction afforded by conduct problem severity alone.

Risk factors

This section reviews potential risk factors for CU traits and conduct problems that occur with CU traits. Whereas genetic differences are causal (although it is important to note, not deterministic!), for the other risk factors the mode of operation is less clear and much of the current research is at a stage of demonstrating an association, without having established the causality of these putative risk factors for CU (see Chapter 12).

Genetic factors

Individual differences in CU are estimated to be moderately to strongly heritable using the twin design that compares resemblance in monozygotic (MZ) twins and dizygotic (DZ) twins in community samples of children and adolescents (heritability estimates from 0.45 to 0.67; see Viding & McCrory, 2012; see also Chapter 24). Having elevated levels of CU is strongly heritable in childhood regardless of whether CU traits are accompanied by conduct problems or not (Larsson *et al.*, 2008). It is also of interest to note that conduct problems with high levels of CU traits appear strongly heritable, whereas conduct problems with low levels of CU traits appear to be more strongly influenced by environmental factors (Viding *et al.*, 2005, 2008; See Figure 68.1).

Twin studies suggest that there is considerable overlap in the genes that influence CU and conduct/externalizing problems, but that there are also unique genetic influences on CU (Forsman *et al.*, 2007; Viding *et al.*, 2007; Bezdjian *et al.*, 2011), consistent with the finding that high levels of CU have been observed in the absence of clinical levels of conduct problems (Frick *et al.*, 2003a; Kumsta *et al.*, 2012). Twin studies also suggest that stability in CU/psychopathic traits is driven by genetic influences (Forsman *et al.*, 2008; Fontaine *et al.*, 2010).

Only a handful of published candidate gene association studies have focused on CU in *children or adolescents* and these studies have tentatively implicated variants in, for example, the serotonin and oxytocin genes (e.g., Fowler *et al.*, 2009; Beichtman *et al.*, 2012; Malik *et al.*, 2012; Dadds *et al.*, 2013; Moul *et al.*, 2013). The current candidate gene studies need to be replicated in larger samples to evaluate whether they report true, replicable associations, but picking candidate genes is not straightforward and can lead to unadjusted multiple testing. Because genetic risk may in many cases only “penetrate” in the presence of environmental risk, genetic studies should carefully document the environmental risk factors in their samples to increase interpretability of the findings and consequently, our understanding of how genetic risk translates to a disorder

Figure 68.1 The main finding from Viding *et al.* (2005), showing the degree to which a group difference in conduct problem scores between typically developing children and 1) children with conduct problems with high levels of callous-unemotional traits (CP/HCU) and 2) children with conduct problems with low levels of callous-unemotional traits (CP/LCU) is due to additive genetic (A), shared environmental (C) and non-shared environmental (E) influences.

outcome. A recent study reported that the long allele of a serotonin transporter polymorphism, the allele reported to confer low amygdala reactivity, was associated with CU in adolescents from low socio-economic status (SES) backgrounds, a finding which was observed in two independent community samples (both rural and urban; Sadeh *et al.*, 2010). These findings suggest that genetic vulnerability to CU traits may only express under unfavourable environmental conditions.

The association studies only considered a limited number of candidate genes. However, a growing number of genome-wide association (GWA) studies for psychiatric phenotypes have shown that genome-wide “hits” are often in genes not previously hypothesized to influence the phenotype or not in traditional genes at all (Visscher *et al.*, 2012). GWA studies systematically scan the genome with hundreds of thousands of DNA markers, made possible by DNA arrays. GWA studies of CU traits suggest that much larger samples will be needed to detect novel associations that account for far less than 1% of the variance (Viding *et al.*, 2010, 2013).

Methods to identify gene–gene and gene–environment interactions (which more than likely account for a proportion of the heritability estimate for psychopathic traits in children) are also required, as is whole-genome sequencing to detect rare variants. Genetic research is likely to advance greatly in the coming decade, including studies using novel epigenetic approaches that may help uncover mechanisms of gene–environment interaction, but it is of critical importance to keep in mind that *there are no genes for CU traits*. Genes code for proteins that influence characteristics such as neurocognitive vulnerabilities that may in turn increase risk for developing CU traits. Genetic variants that are implicated as risk genes for CU traits are likely to include several common polymorphisms that confer advantages, as well as disadvantages, depending on the environmental context. The

neurocognitive vulnerabilities associated with CU traits are at least partially distinct from those associated with conduct problems in general (see Section “Neurocognitive Findings”). This suggests that the risk alleles for CU traits or conduct problems that co-occur with CU traits may not always be the same as risk alleles for conduct problems in the absence of CU traits.

Pre- and peri-natal factors

In contrast to the extensive literature documenting the association between pre- and peri-natal risk factors (e.g., maternal smoking during pregnancy, maternal psychopathology during pregnancy, and birth complications) and conduct problems, the research on pre- and peri-natal risk factors for CU traits (or CP with CU traits) remains extremely sparse. One study to date has reported an association between CU traits (either with or without CP) and maternal psychopathology during and after pregnancy (Barker *et al.*, 2011). However, no data exist to document the role of risk factors such as head injury or infection. This is clearly an area that requires further investigation and it is critical that researchers apply designs that will enable them to evaluate whether the pre- and peri-natal risk factors have a causal role in the development of CU or whether they merely reflect genetic vulnerability within families who have a child with CU traits.

Sex

As outlined in the section on epidemiology in this chapter, high levels of CU traits and CD with CU traits are more common in boys than in girls. There is also nascent research suggesting that the etiology of CU traits may differ for boys and girls (Fontaine *et al.*, 2010). However, the external correlates of high CU traits (e.g., increased conduct problem severity, lower anxiety levels) appear quite similar for both boys and girls (e.g., McMahon

et al., 2010; Pardini *et al.*, 2012). Systematic research investigating potential mechanisms responsible for the differences in prevalence by sex, as well as sex differences in etiological mechanisms, is needed.

Hormonal factors

There is emerging evidence to suggest that males with CU traits are characterized by low levels of basal cortisol (Hawes *et al.*, 2009) and low cortisol reactivity to experimentally induced stress (Stadler *et al.*, 2010). Loney *et al.* (2006) investigated both measures of basal cortisol and testosterone in a non-referred community sample of adolescents. Males (but not females) with high CU traits were found to have low levels of basal cortisol, consistent with similar findings in adults (Cima *et al.*, 2008). Testosterone levels did not differentiate participants in this study and no hormone effects were found for female participants. A recent study of adults reported that an increased testosterone-to-cortisol ratio may particularly characterize individuals high on psychopathic traits (Glenn *et al.*, 2011). This approach, investigating the interconnectedness of different hormone systems, is yet to be extended to children. A study focusing on stress reactivity in children with ADHD found that those with high levels of CU traits showed lowest cortisol response under experimentally induced stress (Stadler *et al.*, 2010).

Physiological factors

Both reduced skin conductance reactivity and reduced heart rate to other people's distress have been reported in children with CU traits and conduct problems, when compared with typically developing peers and peers with conduct problems (Blair, 1999; Anastassiou-Hadjicharalambous & Warden, 2008; de Wied *et al.*, 2012). It appears that resting heart rate does not differentiate children with CU traits (de Wied *et al.*, 2012). Furthermore, skin conductance reactivity is not universally compromised, but appears to be altered in response to distress emotions (Blair, 1999).

Early temperamental factors

Fearlessness and low fear-related arousal have been consistently linked to antisocial outcomes in longitudinal studies (Loeber & Pardini, 2008). Infants and children who display fearless temperament and lack of fearful arousal are also known to show atypical development of empathy and guilt (Fowles & Kochanska, 2000). It has been proposed that fearlessness may be one early temperamental precursor to CU traits, which may interfere with socialization methods that rely on empathy induction (e.g., asking the child to imagine how someone else is feeling) and sanctions (e.g., "time out" or revoking privileges) (Frick & Viding, 2009). In line with this, Barker *et al.* (2011) found that child fearless temperament at age two predicted CU traits at age 13, even after factors such as parenting were controlled for. Thus, fearlessness appears to be an early temperamental factor that predicts development of CU traits in adolescence.

Maltreatment

There are considerable data suggesting that exposure to maltreatment and neglect increases the risk of aggressive/conduct problems (e.g., Caspi *et al.*, 2002; Lansford *et al.*, 2002). Bowlby attributed "affectionless psychopathy" to family adversity that especially involved family disruption (Bowlby, 1946). A recent study with Romanian adoptees demonstrated that extreme childhood neglect is associated with CU traits (Kumsta *et al.*, 2012). Interestingly, although CU traits typically co-occur with conduct problems in community and clinical samples, this was not the case for the adoptees in the study. The authors of this study speculated that adoption to good homes might have reduced the likelihood of conduct problems in the sample or alternatively, that CU traits following neglect were a different, behaviorally equifinal manifestation of CU traits, different from that which is seen in community and clinic samples. Although juveniles with CU traits and conduct problems often report maltreatment histories, we do not currently know whether maltreatment unequivocally causes CU traits. Recent research also suggests that an atypical profile where CU traits co-occur with anxiety is more likely to be associated with maltreatment experiences than CU traits that present without anxiety. It remains to be seen whether the maltreated children who present with CU and anxiety share genetic and neurocognitive characteristics with those children who have CU without anxiety. What we do know is that children who have experienced maltreatment present with neural over- rather than under-reactivity to affective stimuli (e.g., McCrory *et al.*, 2011a, 2013); the opposite of what is typically observed for children with high CU traits (Viding & McCrory, 2012).

Overall, the current literature suggests that for majority of cases, maltreatment produces a neural and behavioral signature that is different from that commonly observed in individuals with conduct problems and CU traits (McCrory *et al.*, 2011b; Danese & McCrory (see Chapter 29); McCrory *et al.*, 2011a). However, it is plausible that both biologically and environmentally "weighted" routes to the same behavioral outcome can take place, even if one route is considerably more common than the other or even if the two routes may differentiate at the level of pathophysiology.

Parenting

There is now substantive evidence that exposure to poor parenting increases the risk for aggression and being diagnosed with CD (Reid *et al.*, 2002). A recent systematic review evaluated the impact of parenting on CU traits in both community and clinic samples (Waller *et al.*, 2013). Harsh and negative parenting was associated with higher levels of CU traits in children, while warm parenting style was associated with lower levels of CU traits in children. However, only one longitudinal, genetically informative study to date has investigated parenting and development of CU traits. This study suggests that the association between harsh and negative parenting and higher levels of CU traits in children may, at least in part, reflect genetic vulnerability within

families (Viding *et al.*, 2009). This could reflect a shared genetic vulnerability to poor parenting and CU temperament, as well as CU temperament evoking negative/harsh parenting.

A number of cross-sectional studies suggest that the dose-response relationship between negative parenting and level of conduct problems does not hold for children with high levels of CU traits, whereas it is commonly observed for other children with conduct problems (reviewed in Waller *et al.*, 2013). Studies on community samples document “what is,” whereas intervention studies document “what can be.” Encouragingly, from a clinical perspective, parenting-focused interventions appear effective in reducing the level of conduct problems and CU traits in children who have high levels of both (Waller *et al.*, 2013; see treatment section of this chapter for further discussion of this issue).

Other risk factors

Factors such as lower SES, IQ and parental psychopathology have all been associated with increased risk for antisocial behavior (see Chapter 65). The data for CU traits specifically are limited. In relation to SES, to our knowledge an association between SES and CU, which cannot be accounted for by other concomitant risk factors, is yet to be established. However, it is important to note that SES could moderate the behavioral manifestation of CU traits. Some antisocial behavior shown by individuals with psychopathic traits is instrumental in nature, it has the goal of gaining another’s money, sexual favors or “respect” (Cornell *et al.*, 1996; Williamson *et al.*, 1987). Individuals can attempt to achieve these goals through a variety of means. Being of a higher SES enables a wider choice of available routes for achieving these goals than being of a lower SES. A healthy individual of limited SES may also have a narrow range of behavioral options but will exclude antisocial behavior because of aversion to this behavior formed during socialization. In contrast, individuals with psychopathy may entertain the antisocial option because they do not find the required antisocial behavior aversive. SES is also likely to impact on the probability of displaying instrumental aggression by determining relative reward levels for particular actions. To illustrate, if the individual already has \$100,000, the subjective value of the \$50 that could be gained if the individual mugged another person on the street is low. In contrast, if the individual has only 50 cents, the subjective value of the \$50 will be very high indeed (for a discussion of subjective value, see Tversky & Kahneman, 1981). In line with this speculation, a recent genetic study found that the long allele of the serotonin transporter gene variant was associated with elevated levels of CU traits, but only in adolescents who lived in low SES families/neighbourhoods (Sadeh *et al.*, 2010).

In relation to IQ, a handful of studies point to a modest negative association between CU traits and IQ (e.g., Fontaine *et al.*, 2008), but the mechanisms of this association are currently unclear. Behavioral problems that are commonly associated

with CU traits may limit educational opportunities of children and contribute to the association.

In relation to parental psychopathology, a positive association between CU traits and parental mental health problems has been demonstrated (e.g., Vizard *et al.*, 2007; Barker *et al.*, 2011). At least one study to date has specifically focused on CU features in mothers and their children and demonstrated a modest intergenerational correlation ($r = 0.22$) (Loney *et al.*, 2007). It is nonetheless of note that this modest correlation is of similar magnitude to that typically observed for different raters (e.g., parent and child) on the same measure—yet it was obtained using different measures and partly different raters (parents for the parent measure; both teachers and parents for the child measure).

Summary—risk factors

An emerging body of research is accumulating that implicates a variety of risk factors associated with the development of CU traits (or conduct problems that occur with these traits)—spanning genetic, physiological, temperamental, ability, and environmental factors. However, we still know relatively little compared to a more substantive empirical evidence base with regard to risk factors associated with conduct problems in general. It appears that children with CU traits have a genetic vulnerability, but less is known about actual genes or how the genetic vulnerability interacts with other risk factors to increase maladaptive outcomes. In order to advance our understanding of risk, longitudinal as well as genetically informative studies with multiple measures of risk are needed to investigate how these interact with each other and whether they are truly causal for the development of CU traits.

Neurocognitive findings

Behaviorally children with CU traits show marked lack of empathy and guilt. They often engage in proactive, instrumental aggression, seem impervious to sanctions, and do not seem to share the affiliative needs and goals that characterize typical children (Frick & Viding, 2009). Given this profile, many of the experimental studies on children with CU traits have focused on how they process emotions, whether they empathize with others, and whether they change their behavior following punishment. These studies have documented that compared with typically developing children or children with other psychopathologies, children with CU traits: are less likely to react to and recognize affective stimuli, particularly distress cues such as fear and sadness of other people (e.g., Marsh & Blair, 2008; Sylvers *et al.*, 2011; however, if specifically directed to focus on the eye region of the face, fear recognition performance can be normalized in these children (Dadds *et al.*, 2008)); show blunted empathy toward others (Jones *et al.*, 2010; Schwenck *et al.*, 2012; de Wied *et al.*, 2012); do not direct attention to the eyes of attachment figures (Dadds *et al.*, 2011; Dadds *et al.*, 2012a);

Box 68.1 Neural circuitry involved in emotion, reward, and empathic processing.**Figure 68.2** Neural circuitry involved in emotion, reward and empathic processing**The amygdala**

The amygdala is a subcortical region that is important for processing the current value of stimuli (Adolphs, 2010). The amygdala has a critical role in several affective processes, such as mediating conditioned emotional responses, responding to various emotional stimuli (including facial expressions of emotion), and in social behavior toward conspecifics (see e.g., Sergerie, Chochol & Armony, 2008; Adolphs, 2010).

The striatum

The striatum is a subcortical region that plays a role in modulating behavior toward potentially rewarding stimuli, particularly stimuli that hold a high subjective reward value to an individual (see e.g., Rosen & Levenson, 2009; Peters & Buchel, 2010).

The anterior cingulate cortex

The anterior Cingulate Cortex (ACC) is thought to play a distinct role in complex aspects of emotion, such as processing moral emotions (e.g., guilt), empathy, self-regulation of negative emotions, and action reinforcement (route by which reward history influences action choice) (see e.g., Levesque *et al.*, 2004; Rushworth *et al.*, 2007; Kedia *et al.*, 2008; Medford & Critchley, 2010).

The anterior insula

The anterior insula (AI) plays an important role in sensory integration (Critchley *et al.*, 2004) and interoceptive awareness (Craig, 2009) and may be involved in awareness of unpleasant feelings during empathy for pain (Medford & Critchley, 2010).

The prefrontal cortex

Various sectors of the prefrontal cortex (PFC) have been implicated in emotion (see e.g., Davidson *et al.*, 2000; Vuilleumier & Pourtois, 2007). The areas that have received most attention in affective neuroscience

studies of children include the orbitofrontal cortex (OFC); ventromedial prefrontal cortex (vmPFC); ventrolateral prefrontal cortex (vlPFC); and dorsolateral prefrontal cortex (DLPFC). The OFC is thought to implement rapid stimulus-reinforcement associations and the correction of these associations when the contingencies of reinforcement change (e.g., Mitchell *et al.*, 2008; O'Doherty, 2004; Rolls & Grabenhorst, 2008), while the vmPFC is thought to represent the elementary positive and negative affective states in the absence of immediately present incentives (Davidson & Irwin, 1999; Mitchell, 2011). A more rostral region of the MPFC has been implicated in the processing of more complex social emotions such as guilt and embarrassment (e.g., Takahashi *et al.*, 2004; Burnett *et al.*, 2009). Current research suggests that vlPFC integrates affective information and supports response selection by increasing the salience of alternative motor response option representations through interactions with the striatum (e.g., Mitchell *et al.*, 2008; Mitchell, 2011). It is also associated with effortful regulation of negative affect, via connections with subcortical structures including the amygdala (Ochsner & Gross, 2005; Wager *et al.*, 2008). DLPFC, in turn, is thought to increase attentional control of task-relevant stimulus features and represent goal states toward which more elementary positive and negative affective states are directed (Mitchell, 2011).

Summary

In this box, we have provided an extremely succinct overview of the brain areas that form the brain's emotional, reward, and empathic circuitry. Clearly, most of the brain's emotional/empathic processes are achieved by functional integration across several brain areas, that is, although broad functions for these brain areas are discussed above, many of these areas work together to achieve appropriate behavioral outcome for the organism. For example, amygdala, together with PFC and ventral striatum, form a network of structures involved in processing the current value of stimuli and various PFC/ACC regions are either directly or indirectly connected with amygdala to achieve emotion regulation via different mechanisms, such as reappraisal.

and are slower to alter their behavior following punishment (e.g., Blair *et al.*, 2001).

The experimental findings that indicate atypical emotion processing and attention to emotion have prompted the study of neural correlates of CU traits (and conduct problems with CU traits) in children, with a particular focus on brain areas associated with emotional, reward and empathic processing. In Figure 68.2 we briefly describe the core emotion, reward and empathy circuitry of the brain for the purposes of anchoring the data presented in this chapter.

Functional magnetic resonance imaging (fMRI) studies

In line with the behavioral and experimental neuropsychology data, fMRI findings for children with CU traits indicate functional deficits consistent with low emotional responsiveness to others' distress and poor ability to learn from reinforcement information. Recent studies have reported reduced amygdala activity to fearful faces in children with conduct problems and high levels of CU traits as compared with typically developing children, children with ADHD, and children with conduct problems and low levels of CU traits (Marsh *et al.*, 2008; Jones *et al.*, 2009b; Viding *et al.*, 2012). Reduced amygdala activity in children with conduct problems and high CU traits also seems to extend to more complex forms of social judgment with regard to other people's distress, such as categorization of legal and illegal behaviors in a moral judgment task (Marsh *et al.*, 2011) or making decisions about appropriate responses to other people's distress (Sebastian *et al.*, 2012). Interestingly, conduct problems with low levels of CU traits appear to be associated with exaggerated, rather than reduced, amygdala activity to emotional stimuli (Viding *et al.*, 2012; Sebastian *et al.*, 2013).

Two recent studies have reported atypical neural reactivity to other people's pain in children with conduct problems and CU traits (Lockwood *et al.*, 2013; Marsh *et al.*, 2013). These studies implicated reduced activity in a network of brain areas associated with empathy for other people's pain in previous studies of healthy individuals, for example, the AI, ACC and amygdala.

Abnormal vmPFC and OFC responses to punishment and reward in children with conduct problems and CU traits have also been reported (Finger *et al.*, 2008; Finger *et al.*, 2011). For example, Finger *et al.* (2008) reported that typically developing children and children with ADHD showed a reduction in vmPFC activity following an unexpected punishment. Such reduction in vmPFC activity has been shown to co-occur with prediction error, that is, when expected outcome differs from the actual outcome (Mitchell, 2011). In contrast, youth with conduct problems and CU traits did not show this reduction in vmPFC activity. In another study, using a passive avoidance paradigm where participants had to learn which stimuli were "good" (rewarded) and which were "bad" (unrewarded), Finger *et al.* (2011) also demonstrated that children with conduct problems and CU traits showed less OFC and caudate responsiveness to early stimulus-reinforcement exposure, and less OFC

responsiveness to rewards. These neural differences are likely to index compromised sensitivity to early reinforcement information in the OFC and caudate and compromised sensitivity to reward outcome information in the OFC in adolescents with conduct problems and CU traits. More recent work, however, suggests that the difficulties in reinforcement learning may not be unique to conduct problems with CU traits, but may instead be a common problem for all children with conduct problems (White *et al.*, 2013).

These fMRI findings in children with conduct problems and CU traits are largely in line with those typically reported in studies of adult psychopaths (e.g., Kiehl *et al.*, 2001; Birbaumer *et al.*, 2005) and suggest functional neural bases for why these children appear unaffected by other people's distress and often make and repeat disadvantageous decisions.

Structural magnetic resonance imaging studies

To date there have been only two studies that report on structural MRI correlates of conduct problems that co-occur with CU traits in children. De Brito *et al.* (2009) found that compared with typically developing boys, boys with conduct problems and high CU traits had increased gray matter concentration (GMC) in several brain areas implicated in decision-making, moral processing, and self-reflection. These included OFC, insula, ACC, posterior cingulate cortex (PCC) and superior temporal cortex.

Subsequently, De Brito *et al.* (2011) showed that compared with typically developing boys, those with conduct problems and CU traits exhibited *decreased* white matter concentration (WMC) in a subset of the brain areas where increased GMC was found in these boys, including ACC and superior temporal cortex. These findings indicate that children with conduct problems and CU traits are characterized by atypical neural structure in many of the same areas where gray and white matter abnormalities have also been reported in adults with psychopathy (Gao *et al.*, 2009; Yang & Raine, 2009). However, somewhat puzzlingly, the direction of the effect (at least for gray matter) is different in the child, as compared with adult studies. It is of note that De Brito *et al.* (2009, 2011) studied children who were between 10 and 13 years of age. Recent brain imaging evidence in normative samples suggests that gray matter decreases and white matter increases in several of the brain areas implicated in the De Brito *et al.* (2009) study during this period of early adolescence (Gogtay *et al.*, 2004). This is contrary to the pattern observed for the 10–13-year-old boys with conduct problems and CU traits, possibly indicative of aberrant brain maturation for this group in early adolescence. More recently, Sumich *et al.* (2012) have found that boys with conduct problems and CU traits do not show the typical maturational pattern of decline in the event-related potential component N200 amplitude in midline frontal and temporal electrodes, further evidencing a possible atypical maturation for this group of boys. These data are not necessarily at odds with the findings from adult studies, which clearly represent a very different developmental stage. Distinct developmental disorders can follow markedly

different patterns of structural brain development (Shaw *et al.*, 2010) and future longitudinal studies should probe the exact developmental pattern characteristic of conduct problems and CU traits.

Summary—neurocognitive findings

The extant magnetic resonance imaging evidence base suggests that conduct problems with CU traits are associated with atypical patterns of brain structure and function, particularly in the areas critical for affective processing, affective decision-making, and moral emotions. The findings are broadly in line with those reported in studies of adult psychopaths and may represent neural indicators of vulnerability that render these children at increased risk for developing adult psychopathy.

Treatment implications

Conceptually, children with conduct problems and high levels of CU traits would be hypothesized to respond differentially to treatment, given their distinct pattern of etiological and neurocognitive vulnerability. These children have genetic vulnerability to antisocial behavior and show functional and structural neural abnormalities that may predispose them to atypical development of emotion processing, reinforcement learning, and empathy. Only relatively recently have studies begun to examine how treatment outcome might vary in relation to a child's level of CU traits, and whether the efficacy of treatment strategies vary depending on level of CU traits.

There is now growing evidence that children with high levels of CU traits benefit significantly from standard interventions (Waller *et al.*, 2013). While they are likely to enter and finish treatment with more pronounced behavioral and social difficulties, they can show real improvements. For example, Kolko and Pardini (2010) found that a sample of clinic-referred children with conduct problems and high CU traits who received a wide range of individualized and modular interventions (e.g., parent training, cognitive behavioral therapy, peer relationship development, medication for ADHD) improved at a similar rate to other children with conduct problems. Similarly, Caldwell and colleagues (2006) evaluated an intensive treatment program of incarcerated juvenile offenders that utilized reward-oriented approaches focusing on the interests of the adolescent and aimed to develop empathy skills. Juvenile offenders with high levels of CU traits were less likely to recidivate after a 2-year follow-up period compared to their peers with high CU traits allocated to a treatment as usual intervention. More recently, White and colleagues (2013) have reported significant improvements in behavioral and emotional domains following an evaluation of Functional Family Therapy delivered over 3–5 months (average of 10 sessions) in adolescents with high levels of conduct problems and CU traits. Future studies using randomized control designs are needed.

Although traditional treatments appear to work with children who have conduct problems and high levels of CU traits, these children typically enter treatment with the most severe behavioral presentations and even after improvement following treatment, often continue to present with ongoing problematic and concerning behaviors. More systematic research is required to pinpoint the specific components of existing treatments that work more or less effectively for these children in order to guide clinical practice. New treatment modules focusing on specific areas of functioning known to be problematic in children with high levels of CU traits appear promising. In a recent randomized controlled trial by Dadds *et al.* (2012b) treatment-as-usual (TAU) was evaluated with or without the adjunctive emotion recognition training (ERT), where the TAU comprised a fully manualized parent training program based on well-established parenting components. While ERT did not have an effect on the group as a whole, children with higher levels of CU traits (even those without a diagnosis of CD) showed more improvement in affective empathy and reduced conduct problems in response to ERT. Conversely, a number of parenting intervention studies suggest that children with high levels of CU traits may respond less well to some aspects of standard parenting interventions than their conduct problem peers with low levels of CU traits. For example, observational data relating to the parent–child interactions in the home in a standard 10-week parenting programme indicated that those children with high CU traits were less responsive to the “time-out” procedure, suggesting differential responsiveness to this traditional treatment component. This finding is consistent with the evidence from the experimental literature indicating that these children may be relatively punishment-insensitive (Frick & Viding, 2009). However, reward-based strategies appeared to be equally effective for all children with conduct problems in the Hawes and Dadds (2005) study.

These preliminary findings provide a promising basis for future programmes to incorporate tailored treatment strategies for children with higher levels of CU traits where specific components are added or removed from traditional treatment protocols. In relation to parenting programmes, it may be of interest to develop a component where parents are supported and scaffolded to respond in an enhanced positive manner. Given that previous parenting studies suggest that these children respond to warm parenting (Waller *et al.*, 2013), but can also evoke negative parental reactions (Hawes *et al.*, 2011), part of the clinical task is to be particularly mindful of fostering positive parental responses in a context where there may be sparse triggers for such responses from the child (e.g., the children do not appear to initiate eye contact with attachment figures; Dadds *et al.*, 2012b). More generally, it may be beneficial to nuance treatment targets with the child, such that they are in line with the child's self interest (where feasible and appropriate); heightened self interest is a pronounced feature of children with high levels of CU traits. Finally, it is noteworthy that behavioral interventions are increasingly being delivered

in school settings (Viding *et al.*, 2011). Given that children with conduct problems and high CU traits often come from families characterized by multiple difficulties (where parents are also likely to have genetic and neurocognitive vulnerabilities), school settings may provide an important context, within a broader systemic intervention, for delivering consistent intervention

Summary—treatment

Although children with conduct problems and high levels of CU traits present with a distinct pattern of neurocognitive vulnerability, they appear to respond to traditional treatment approaches. However, given these children typically have more severe and enduring difficulties as well as a higher drop-out rate, there is a need to optimize or tailor our treatment approaches to improve outcomes for this subgroup of children. Preliminary findings suggest that some traditional treatment components (such as time out) are less effective with this group, while others (such as positive parenting and ERT) may be helpful to incorporate or enhance within traditional treatment models.

Future developments and necessary research

Although our understanding of developmental vulnerability to psychopathy has increased substantially over recent decades, several important avenues of research remain outstanding. CU traits can now be used as a specifier when diagnosing CD in children (“limited prosocial emotions”). The next decade of research and clinical practice will show how successful the DSM-5 specifier criteria are in delineating a meaningful subgroup of children with CD. Although more research into risk factors for CU traits is required, there is also a need to move from risk factor documentation to understanding whether all of the proposed risk factors are causal, what the mechanisms by which they increase risk for CU traits are and whether they are modifiable. Longitudinal research utilizing multiple methodologies within a genetically informative framework is required to really advance our understanding of risk and protective mechanisms that are important. Related to this quest, and because we know that CU traits (and conduct problems with CU traits) are heritable, there is a challenge to find genes that increase risk for CU traits. In the coming years we are likely to discover that some of the polymorphisms we thought were important simply represent false positives and others, which at first sight appeared less intuitive, may represent true genetic risk. Similarly, we do not know very much about environmental factors that increase vulnerability to CU traits (and conduct problems with CU traits). It will be important for future studies to investigate both mothering and fathering over time and to tease out whether, for example, parenting factors represent true environmental risk factors or genetic vulnerability within families. Addressing such questions effectively represents a challenge to basic research, but further advances in this field will help us better understand how risk factors in childhood may lead to the development of psychopathy in adulthood. We

think that a better delineation of (even putative) causal mechanisms has the potential to inform more effective approaches to prevention and treatment for at-risk children. Although it will be helpful to examine what aspects of current treatments best work for children with conduct problems and high CU traits, development of new treatment components and strategies will benefit from insights gained from basic science studies. These will include investigations to the degree to which the emotional impairments seen in children with CU traits are fixed, or may be either ameliorated or compensated for by both effortful and also more implicit strategies (see e.g., Dadds *et al.*, 2008).

Finally, a few recent studies suggest that CU traits may be an important clinical indicator even in the absence of conduct problems (e.g., Rowe *et al.*, 2010; Kumsta *et al.*, 2012). Research is clearly needed to follow up children who have high levels of CU traits, but who do not qualify for a diagnosis of CD. We do not currently know if these children have a similar neurocognitive profile to their peers with CU traits and conduct problems. We also do not have good data on how they fare in adulthood.

Conclusions

Developmental risk for psychopathy is currently indexed by diagnosing conduct problems with CU traits (“limited prosocial emotions” in DSM-5). Behaviorally, children with this presentation are characterized by severe and proactive antisocial and violent behavior and little concern for the feelings or welfare of other people. Children with conduct problems and CU traits appear genetically vulnerable to conduct problems, although the precise nature of genetic risk and how it may operate together with environmental risk factors is currently unknown. However, it is encouraging and worth emphasizing that children with conduct problems and CU traits appear to benefit from parenting treatments. The challenge for the next 10 years is to delineate more precisely what works for these children and how current intervention and prevention programmes might be optimized in ways that would improve engagement as well as clinical outcomes. For example, experimental psychology and neuroimaging work indicate that children with conduct problems and CU traits have an attenuated response to other people’s distress and pain and do not readily learn from punishment (and to some extent reward). These basic science findings suggest that some socialization techniques, such as empathy induction and punishment, may have more limited success with this group of children. Further research determining the degree of malleability in how these children process affective information, as well as possible compensatory cognitive-affective functions that could be harnessed to scaffold any atypical processing, will be important next steps in informing how traditional programmes of intervention can be modified and enhanced. There is every reason to be optimistic in this regard, but it will require a step-change in how basic science and clinical practice researchers collaborate, if we are to make genuine progress.

CHAPTER 69

Gender dysphoria and paraphilic sexual disorders

Kenneth J. Zucker¹ and Michael C. Seto²

¹ Centre for Addiction and Mental Health, Toronto, Ontario, Canada

² Royal Ottawa Health Care Group, Integrated Forensic Program, Brockville, Ontario, Canada

Introduction

This chapter provides a review of two distinct diagnostic conditions: gender dysphoria (GD) in children and adolescents and paraphilic sexual behavior (primarily sexual offenses against children) in adolescents. For each condition, the phenomenology is reviewed. In the case of GD, there has been a major shift in conceptualization, which is now reflected in the wording of the diagnostic criteria. For each condition, the following sections review the available assessment measures before considering associated psychopathology and its correlates as well as sex differences in referral rates. Next, the knowledge bases concerning the known biological and psychosocial risk factors are summarized. For each disorder, the final section focuses, from a developmental perspective, on the currently available therapeutic approaches to clinical management.

Gender dysphoria (GD)

Characteristics and diagnosis of the condition

Phenomenology

Children with GD display behaviors that reflect identification with the other sex (Zucker & Bradley, 1995). For children with GD referred before age 12, most such behaviors onset between ages 2–4 (Ruble *et al.*, 2006). In patients first observed in adolescence, history is more varied, with some onsets in early childhood and others at later ages, typically around puberty (Zucker *et al.*, 2012a). This suggests the presence of early-onset and late-onset forms. In the early-onset form for biological males, sexual orientation is almost always homosexual (androphilic); in the late-onset form, it is almost always nonhomosexual and often co-occurs with transvestic fetishism (with or without autogynephilia—sexual arousal associated with the thought or image of oneself as a woman) (Blanchard, 2010).

In biological females, the early-onset form is typically associated with a homosexual (gynephilic) sexual orientation and, in the late-onset form, is typically nonhomosexual (see Lawrence, 2010).

Normal and pathological behaviors

Youth with GD show overt sex-typed behavior that is “inverted” in relation to their natal sex peers. This can be described as “gender variant” or “gender nonconforming,” which some suggest is not necessarily pathological (Gray *et al.*, 2012; Giordano, 2013). There is, however, some consensus in considering GD abnormal when it is associated with significant distress with regard to their felt gender. It is more difficult to consider a strong desire to alter the body to conform to the felt psychological state in adolescent or adult GD a form of normative variation.

GD occurs in many cultures, with remarkable phenomenological similarity. Many non-Western cultures have coined terms to describe what appear to be equivalents to GD and “transsexualism” in modern societies.

DSM-5 and the ICD

DSM-5 treats GD substantially differently from the DSM-IV-TR (see Zucker *et al.*, 2013):

- 1 The label was changed from gender identity disorder (GID) to GD, which is considered a more accurate term (Fisk, 1973) and which highlights the salience of “distress” (dysphoria) (Knudson *et al.*, 2010). There was considerable support for this change related to a reduction in stigma (Vance *et al.*, 2010).
- 2 In DSM-5, GD has its own chapter and thus has been decoupled from the sexual dysfunctions and paraphilias, which also have their own chapters. This reflected incomplete overlap among these conditions. Although GD co-occurs with one paraphilia, transvestic disorder (Blanchard, 2010), the advantages of this change outweighed the disadvantages.

- 3 The Point A diagnostic criterion (which lists the symptoms) introduced a conceptual shift by emphasizing “incongruence” between one’s experienced/expressed and assigned gender, as opposed to “cross-gender identification” in DSM-IV-TR.
- 4 The GD criteria for children require “... a strong desire to be of the other gender or an insistence that he or she is the other gender (or some alternative gender different from one’s assigned gender).” This could sharpen distinctions between GD and normative variation (see Zucker, 2010).
- 5 Whether individuals born with a physical intersex condition (now termed a disorder of sex development) (DSD) should be eligible for a diagnosis if GD is contentious (see Meyer-Bahlburg, 1994). Recent evidence suggests that some individuals with a DSD experience GD (Richter-Appelt & Sandberg, 2010; Pasterski *et al.*, 2014) and these individuals only share some features with individuals with GD without DSD (American Psychiatric Association, 2013, pp. 455–456). DSD appears as a specifier in DSM-5.
- 6 For adolescents (and adults), a DSM-IV-TR specifier for sexual attraction was eliminated, a controversial decision. Sexual orientation in GD does clearly relate to many clinical features (see Zucker *et al.*, 2012a) and may also identify specific mechanisms generating GD (Lawrence, 2010). However, sexual orientation minimally influences treatment (Cohen-Kettenis & Pfäfflin, 2010) and may not reflect a difference in symptom expression of GD, a key feature of other DSM-5 specifiers.

The ICD-10 (World Health Organization, 1992) has a section on GIDs (F64) resembling DSM-IV-TR. It includes the categories of Transsexualism and Gender Identity Disorder of Childhood. Plans for ICD-11 remain in the proposal stage (Drescher *et al.*, 2012).

Assessment

Many scales are useful to assess GD in children (Zucker, 2005a; Zucker & Wood, 2011). Most show good discriminant validity, sensitivity, and specificity. Moreover, among gender-referred children, these measures can discriminate threshold versus subthreshold GD. Updated scales continue to show strong psychometrics (Zucker & Wood, 2011; Zucker *et al.*, 2012a). The Gender Identity/Gender Dysphoria Questionnaire for Adolescents and Adults is one particularly useful measure (Singh *et al.*, 2010).

Youth with GD show high rates of various forms of psychopathology relative to comparison groups. This has been documented most systematically using the Child Behavior Checklist (CBCL), the Teacher’s Report Form (TRF), and the Youth Self-Report (YSR) form (Zucker & Bradley, 1995; Cohen-Kettenis *et al.*, 2003; Zucker *et al.*, 2012a; Steensma *et al.*, 2014) (for review, see Zucker *et al.*, 2014).

Behavior problems increase with age in boys with GD (Cohen-Kettenis *et al.*, 2003; Steensma *et al.*, 2014). Youth with GD experience significant peer difficulties (Zucker *et al.*, 1997a; Cohen-Kettenis *et al.*, 2003; Wallien *et al.*, 2010; Shiffman, 2013) and peer difficulties relate to behavior problems (Cohen-Kettenis *et al.*, 2003; Steensma *et al.*, 2014). Recent

interest focuses on possible co-occurrence with autism spectrum disorders (ASD) (see de Vries *et al.*, 2010) or at least the presence of intense unusual interests, in this context, to do with gender (see VanderLaan *et al.*, 2015). Thus, assessment of GD requires the consideration of a broad range of psychopathology.

Epidemiology

Prevalence

Contemporary, large-scale epidemiological studies have not examined GD. Estimates of prevalence, therefore, emerge from other less-sophisticated sources, such as rates of treatment seeking. Overall, recent estimates suggest a prevalence of 0.005–0.014% in natal males and 0.002–0.003% in natal females (Zucker & Lawrence, 2009; American Psychiatric Association, 2013). Compared to older estimates, these figures have been interpreted as reflecting a notable increase in adults with GD (Coleman *et al.*, 2011). In a recent community-based US study (Shields *et al.*, 2013), 1.3% of youth in Grades 6–8 self-identified as transgender, although it is unclear how these rates relate to rates of DSM-5 GD.

Sex differences in referral rates

Among children between the ages of 3 and 12, boys are referred clinically more often than girls for concerns regarding gender identity. From one specialty clinic in Toronto, Canada, Wood *et al.* (2013) reported a sex ratio of 4.49:1 ($N = 577$) of boys to girls based on consecutive referrals from 1976 to 2011. Comparative data from the sole gender identity clinic for children in Amsterdam, The Netherlands also favored referral of boys over girls, but the sex ratio was smaller (2.02:1, $N = 468$).

Although the sex ratio favoring boys may reflect a bona fide sex difference in prevalence, social factors may also play a role. Parents, teachers, and peers are less tolerant of cross-gender behavior in boys than in girls, which might result in a sex-differential in clinical referral (Zucker & Bradley, 1995; Wallien *et al.*, 2010). This appears to be particularly the case with relatively younger children; for example, Wood *et al.* (2013) reported a markedly skewed sex ratio of 33:1 of referred GD boys to girls among 3-year-olds, which gradually dropped to almost parity by age 12.

Referral rates of GD adolescents may be increasing. In the Toronto clinic, referral rates of adolescents between 2008 and 2011 showed a fivefold increase in magnitude compared to referred adolescents in 2000–2003 (Wood *et al.*, 2013). Various explanations for this increase have been posited, including the destigmatization of gender-variant behavior and increased attention in media (Zucker *et al.*, 2008).

Risk factors

Molecular and behavior genetics

Candidate gene studies have yielded mixed results and failures to replicate (Ngun *et al.*, 2011). However, there is some supportive behavior genetic evidence: in clinical samples, identical

twins are more likely to be concordant for GD than nonidentical twins (Heylens *et al.*, 2012; for a nonclinical sample, see Coolidge *et al.*, 2002). Moreover, in the general population, twin studies have shown that the liability for cross-gender behavior has a strong heritable component (van Beijsterveldt *et al.*, 2006). Other studies, however, have also identified strong shared and nonshared environmental influences (Iervolino *et al.*, 2005; Knafo *et al.*, 2005). Such environmental influences could, of course, pertain to nongenetic biological factors but could also involve postnatal psychosocial factors.

Prenatal sex hormones

Considerable research examines effects of prenatal sex hormones on sex-dimorphic behaviors (Baum, 2006). In humans, influence of prenatal sex hormones and rearing effects are hard to disentangle; accordingly, researchers have relied on children born with DSDs to separate out the relative influence of biological and psychosocial processes on psychosexual differentiation.

This research provides considerable evidence for an influence of prenatal sex hormones on postnatal sex-dimorphic behavior. For example, chromosomal females with congenital adrenal hyperplasia (CAH), who are exposed to sex-atypical levels of prenatal androgen, show more masculinized gender role behavior in childhood and adolescence and a higher rate of a bisexual/homosexual sexual orientation in adulthood (Zucker, 1999; Hines, 2004; Cohen-Bendahan *et al.*, 2005). Although most females with CAH show a sex-typical gender identity (Meyer-Bahlburg *et al.*, 2004; Dessens *et al.*, 2005), there is also evidence that GD is elevated compared to population base rates (Pasterski *et al.*, 2014).

Most youth with GD do not have a DSD. Accordingly, the search for biological influences on the development of GD must focus on factors that do not affect the configuration of the external genitalia. Prenatal hormonal influences may play a role, but there would have to be some kind of brain-genital dissociation in their impact (e.g., perhaps due to timing effects) (Goy *et al.*, 1988). Given that there are no post-mortem studies on brain neuroanatomy in GD children or youth, research has focused on various other biological factors.

Temperament

Activity level (AL) is a dimension of temperament with some evidence for a genetic basis and possibly prenatal hormonal influences (Campbell & Eaton, 1999). In general, boys have a higher AL than girls. Parents report lower levels of AL in boys with GD compared with controls (Bates *et al.*, 1979; Zucker & Bradley, 1995). Zucker and Bradley also found that girls with GD had a higher AL than control girls. It is possible that a sex-atypical AL is a temperamental factor that predisposes the development of GD. For example, a low-active boy with GD may find the typical play behavior of other boys to be incompatible with his own behavioral style, which might make it difficult for him to integrate successfully into a male peer group.

Sibling sex ratio and birth order

Compared to the sex ratio at birth in the general population, boys with GD have an excess of brothers to sisters (sibling sex ratio) and a later birth order. Moreover, other evidence shows that boys with GD are born later in relation to the number of older brothers (the “fraternal” birth order effect), but not sisters (Blanchard *et al.*, 1995; Zucker *et al.*, 1997b; Schagen *et al.*, 2012; VanderLaan *et al.*, 2015). In the Blanchard *et al.* study, clinical control boys showed no evidence for an altered sibling sex ratio or a late birth order nor did adolescent boys with transvestic fetishism (VanderLaan *et al.*, 2015). VanderLaan *et al.* established that the late fraternal birth order of GD males was specific to those with a homosexual sexual orientation in relation to birth sex, similar to what has been found in adult GD males with a homosexual sexual orientation, who also have an excess of brothers to sisters and a later birth order (Blanchard, 1997). Collectively, these studies show that the fraternal birth order effect in GD males parallels the same finding in homosexual men without GD (Bogaert & Skorska, 2011).

Psychosocial risk factors

Psychosocial factors must be shown to influence the emergence of marked cross-gender behavior in the first few years of life. Otherwise, such factors would be better conceptualized as perpetuating rather than predisposing to GD.

Social reinforcement

The parental response to early cross-gender behavior is usually not negative (Roberts *et al.*, 1987; Zucker & Bradley, 1995). Green (1974) concluded that “what comes closest so far to being a *necessary* variable is that, as any feminine behavior begins to emerge, there is *no* discouragement of that behavior by the child’s principal caretaker” (p. 238, italics in original). The reasons for this response are diverse, as discussed elsewhere (Zucker & Bradley, 1995; Ehrensaft, 2011).

Cognitive-developmental factors

Cognitive factors may shape gender development (Martin *et al.*, 2002; Tobin *et al.*, 2010). Two elements appear relevant. First, early gender self-labeling may organize monitoring of social information in GD children, due to a “developmental lag” in cognitive gender constancy that leads to mislabeling (Zucker *et al.*, 1999; Wallien *et al.*, 2009). Such early cognitive mislabeling could support some kind of interactive effect between cognitions and cross-gendered behavior. Second, some young children may have rather rigid interests in sex-typed behavior: for girls, Halim *et al.* (2014) dubbed this the “pink frilly dress” phenomenon. Halim *et al.* argued that this gender rigidity was part of the young child’s effort to master gender categories and to securely (affectively) place oneself in the “right” category. Parents of such children do not particularly encourage the rigidity, but they also do not discourage it and there is the assumption that such rigidity will wane over developmental time and that there will be a concomitant increase in gender

flexibility. Other data support this possibility (VanderLaan *et al.*, 2015). The response to these early features could modulate the long-term course of cross-gender identity.

General psychopathology

Considerable research focuses on maternal psychopathology in GD. Both Marantz and Coates (1991) and Zucker (2005b) found higher rates of psychopathology, particularly emotional disorders, in mothers of boys with GD than comparison boys. Although psychopathology is elevated, this may reflect a non-specific risk factor, as similar findings occur in other disorders. Other work focuses on specificity in family factors, such as father absence, in GD. Across 10 samples of boys with GD, the rate of father absence was 34.5% (Zucker & Bradley, 1995) although this rate may not differ from other clinical populations. Green (1987) found that paternal separations occurred earlier in the families of boys with GD than healthy boys; therefore, it is possible that timing is an additional variable to consider.

Developmental trajectories

Boys

Two recent studies by Wallien and Cohen-Kettenis (2008, $n = 59$) and Singh (2012, $n = 139$) document outcome in boys. Wallien and Cohen-Kettenis found a GD persistence rate of 20.3% and Singh found a persistence rate of 12.2%. Regarding sexual orientation, a substantial majority (63.6–81%) was homosexual/bisexual in fantasy and at least half were homosexual or bisexual in behavior.

Girls

With regard to girls, data remain meager. Drummond *et al.* (2008, $n = 25$) and Wallien and Cohen-Kettenis (2008, $n = 18$) reported the first follow-up studies. Wallien and Cohen-Kettenis found a GD persistence rate of 50%, but Drummond *et al.* reported a persistence rate of only 12%. Regarding sexual orientation, Wallien and Cohen-Kettenis reported that 70–100% (depending on the metric) were homosexual/bisexual in fantasy whereas Drummond *et al.* reported a corresponding value of 32%. In behavior, the corresponding percentages for the two studies were 60% and 24%, respectively.

Predictors of long-term gender identity

When one asks adolescents or adults with GD about their recollections of sex-typed behavior in childhood, for those who have a sexual orientation directed to members of their birth sex, it is almost universal to find a childhood history of marked gender-variant or cross-gender behavior (Deogracias *et al.*, 2007; Singh *et al.*, 2010). By contrast, the prospective data summarized earlier show much less continuity. Plasticity may be one explanation for this discrepancy. It is possible, for example, that gender identity shows relative malleability during childhood, with narrowing plasticity with age. Another explanation relates to historical factors (see Zucker *et al.*, 2012b), related to the gender-transition movement (Meadow, 2011) and

views of early cross-gender identification that encourage early social transition (Byne *et al.*, 2012).

In three major follow-up studies, dimensional measures of cross-gender identity and cross-gender role behavior in childhood predicted GD persistence. Children whose cross-gender identity and behavior was more extreme were more likely to be persisters. Some evidence also suggests that children from “working class” backgrounds possess earlier awareness of “sex-appropriate” behavior than children from middle-class backgrounds (Rabban, 1950). Singh (2012) also described social class related difference in GD boys from lower SES families had more “rigid” notions of within-sex variation in sex-typed behavior and that could moderate outcome.

Ethical considerations

Consider the following clinical vignettes:

- 1 A mother of a 4-year-old girl contacts a well-known clinic that specializes in gender identity throughout the life span. She describes behaviors consistent with the DSM-5 diagnosis of GD. The clinician tells the mother: “Well, we don’t consider ‘it’ to be a problem.” The mother then contacts another specialty clinic and asks “What should I do?”
- 2 A mother of a 4-year-old boy contacts a well-known clinic that specializes in gender identity problems. She describes behaviors consistent with the DSM-5 diagnosis of GD. She says that she would like her child treated so he does not grow up to be gay. She also worries that her child will be ostracized within the peer group because of his pervasive cross-gender behavior. What should the clinician say to this mother?
- 3 A 15-year-old adolescent girl with GD asks to be seen for treatment. She would like cross-sex hormones and a mastectomy immediately. If refused, the patient says that she will kill herself. What should the clinician do?
- 4 A 16-year-old adolescent boy with GD asks for sex-reassignment surgery. He states that he is sexually attracted to biological males and wants a sex-change because that will make his sexual feelings for males “normal.” He states that homosexuality is against his religious beliefs and is taboo in his culture of origin. What should the clinician do?

Treatment

No randomized controlled trials exist for GD (Byne *et al.*, 2012). The few treatment-effectiveness studies lack methodological sophistication. This leaves practitioners to rely on “clinical wisdom” (for an overview, see the special issue of the *Journal of Homosexuality* on “The Treatment of Gender Dysphoric/Gender Variant Children and Adolescents” [Drescher & Byne, 2012]). In an era that emphasizes evidence-based therapeutics, this is a source of frustration (Zucker, 2008; Dreger, 2009).

Behavior therapy

There are 13 published single-case reports on behavior therapy in pediatric GD (see Zucker, 1985). Some interventions use so-called *differential social attention* or *social reinforcement*,

applied in clinic settings. The therapist first establishes that the child prefers playing with cross-sex toys or dress-up apparel rather than same-sex toys or dress-up apparel. A parent or stranger is then introduced into the playroom and instructed to attend to the child's same-sex play and to ignore the child's cross-sex play, which can change play behavior.

This approach may not generalize to other settings or other untreated cross-sex behaviors (Rekers, 1975). Such problems led behavior therapists to seek more effective strategies of promoting generalization. One such strategy, *self-regulation* or *self-monitoring*, has the child reinforce himself or herself when engaging in a sex-typical behavior. Although self-monitoring also resulted in substantial decreases in cross-sex play, the evidence is weak that generalization is better promoted by self-regulation than by social attention (Zucker, 1985).

No case reports have appeared for over 30 years, which is curious, because similar approaches are used widely for many other problems. Behavior therapy with an emphasis on the child's cognitive representations of gender could be useful, possibly incorporating work on cognitive gender schemas in typically developing children (Martin *et al.*, 2002). It is possible that children with GD have more elaborately developed cross-gender schemas than same-gender schemas and that more positive affective appraisals are differentiated for the former than for the latter (e.g., in boys, "girls get to wear prettier clothes" vs "boys are too rough"). A cognitive approach could target such features to produce positive gender-related feelings.

Psychotherapy

There is a large case report literature on GD using other approaches (see Zucker, 2007). This uses varied theoretical approaches, but this literature has not produced a clinical trial.

Parental engagement

Two rationales support parental involvement. First, parental behavior could initiate or sustain GD. From this perspective, individual therapy with the child could benefit by also helping parents gain insight into these behaviors, as discussed elsewhere (Newman, 1976; Zucker, 2006; Zucker *et al.*, 2012b). Second, parents will benefit from therapist contact to discuss day-to-day management, set limits with regard to cross-gender behavior, and encourage same-sex peer relations and gender-typical activities (see Meyer-Bahlburg, 2002).

Although clinicians typically work with parents of children with GD, there is scant empirical evidence on efficacy. Observational data support the practice, but no randomized controlled trial exists (Zucker *et al.*, 1985).

In Example 2 noted earlier, a parent such as this will likely be receptive to a therapeutic approach that attempts to reduce the GD even with the clear caveat by the clinician that the aim of such an approach is not designed to change the child's sexual orientation, for which there is no empirical evidence (Green, 1987).

Supportive or "gender-affirming" treatments

In the past few years, clinicians critical of conceptualizing marked gender-variant behavior in children as a disorder have provided a dissenting perspective to the treatment approaches described so far (e.g., Menvielle & Tuerk, 2002; Hill & Menvielle, 2009; Menvielle, 2009, 2012; Ehrensaft, 2011). These clinicians conceptualize GD or pervasive gender-variant behavior from an essentialist perspective—that GD is largely constitutional or congenital in origin—and are skeptical about the role of psychosocial or psychodynamic factors in its genesis or maintenance. For example, Menvielle and Tuerk (2002) noted that, while it might be helpful to set limits on pervasive cross-gender behaviors that may contribute to social ostracism, their primary treatment goal was "...not at changing the children's behavior, but at helping parents to be supportive and to maximize opportunities for the children's adjustment" (p. 1010). This perspective, therefore, appears to encourage some parents to take an approach that is rather different from the more conventional therapeutic models. As noted earlier, there is a burgeoning gender-transition movement that involves both professionals and parents who utilize this approach, which has received widespread media attention (including US celebrities such as Anderson Cooper and Barbara Walters) and on the Internet, with various examples of parental narratives describing their experience in helping their children in this way (e.g., Kelso, 2011; Wisnowski, 2011). In Example 1 noted earlier, it is clear that the practicing clinician would be most sympathetic with this philosophical and conceptual approach in dealing with the child's GD. In the current therapeutic climate in which disagreement about best practice is marked (Byne *et al.*, 2012), some parents will be most drawn to this approach, but others will not be.

Treatment of adolescents

In adolescents with GD, there are three broad clinical issues that require evaluation: (i) the phenomenology pertaining to the GD itself, (ii) sexual orientation, and (iii) psychiatric comorbidity. For the majority of adolescents, clinical experience suggests that the GD will desist only after the patient has made a social transition to the desired gender and to be treated biomedically with hormone therapy and sex-reassignment surgery. However, there are some adolescents who present clinically with a less stable, and more fluctuating cross-gender identity, and these youth are probably best treated first in psychosocial therapy in order to explore the extent to which a gender social transition is going to prove helpful. It is also important to understand the patient's sexual orientation, as the intersection between the adolescent's gender identity and to whom one is attracted to have important implications for the establishment of interpersonal, romantic relationships. Because many adolescents with GD have other psychosocial and psychiatric problems that they are struggling with, it is important to have a good understanding of how these difficulties impact their general functioning and well-being (de Vries *et al.*, 2011a; Zucker *et al.*, 2011).

The psychotherapy treatment literature on adolescents with GD has been very poorly developed and is confined to a few case reports (Zucker & Bradley, 1995; Rosario, 2009). In general, the likelihood of GD persistence for adolescents is much higher than it is for children (Zucker *et al.*, 2011). From a clinical management point of view, two key issues need to be considered: (i) some adolescents with GD are not particularly good candidates for therapy because of comorbid disorders and life circumstances; (ii) the majority of adolescents wish to proceed with hormonal and surgical sex reassignment as part of their desire to live socially in the preferred gender. Some of these youth are also interested in some type of psychosocial therapy to help them with the process of gender transition and/or to help them deal with other psychologic and psychiatric issues that they may be struggling with.

Before recommending hormonal and surgical interventions, many clinicians encourage adolescents with GD to consider alternatives. One area of inquiry can, therefore, explore the meaning behind the adolescent's desire for sex reassignment and if there are viable alternative lifestyle adaptations. The most common area of exploration in this regard pertains to the patient's sexual orientation. Some adolescents with GD recall that they always felt uncomfortable growing up as boys or as girls, but that the idea of "sex change" did not occur until they became aware of homoerotic attractions. For some of these youth, the idea that they might be gay or homosexual is abhorrent (as noted in Example 4 earlier). If those issues are worked through, the GD will lessen, if not remit. If the issues do not remit, then biomedical treatment may well be warranted.

For adolescents in whom the GD appears chronic, there is considerable evidence that it interferes with general social adaptation, including general psychiatric impairment, conflicted family relations, and dropping out of school (see the section on Associated Psychopathology on page 989). For these youth, therefore, the treating clinician can consider three main options: (i) in early adolescence, the institution of hormonal therapy with gonadotropin-releasing hormone (GnRH) analogs to delay or suppress somatic puberty; (ii) subsequent initiation of cross-sex hormonal therapy; and (iii) surgical sex change at a lower bound age of 18 (Delemarre-van de Waal & Cohen-Kettenis, 2006; Cohen-Kettenis *et al.*, 2011; Zucker *et al.*, 2011). It has, for example, been argued that institution of GnRH treatment makes it easier to "pass" as the opposite sex. Thus, for example, in male adolescents, such medication can suppress the development of secondary sex characteristics, such as facial hair growth and voice deepening, which make it more difficult to pass in the female social role.

Over the past number of years, emerging evidence suggests that the institution of puberty-blocking hormone therapy and cross-sex hormone therapy facilitates a reduction in GD and improves psychosocial and psychiatric well-being in carefully selected patients (Cohen-Kettenis & van Goozen, 1997; Smith *et al.*, 2001; de Vries *et al.*, 2011b). In Example 3, however, biomedical treatment would not be recommended until the patient was more stable and less at-risk for "acting out."

Although it would be desirable to design a randomized controlled trial in which an alternative arm would be a psychosocial treatment aimed at reducing the patient's GD (without any concomitant biomedical intervention), such a design is probably not feasible because it would be difficult, if not impossible (for both practical and ethical reasons), to randomly assign patients to the two types of treatment. An alternative design might include a waiting list control group to see if the GD persists over at least a short-term period of time (say, e.g., 6 months). Although hormonal treatment for GD in adolescents has been deemed controversial (Beh & Diamond, 2005; Giordano, 2013), it appears to be a successful evidence-based treatment and may well be the treatment of choice once the clinician is confident that other options have been ruled out.

Paraphilic sexual disorders

Characteristics and diagnosis of the condition

Phenomenology

Paraphilias can be classified into those that involve atypical sexual targets or activities. Atypical targets include sexually immature persons (pedophilia), nonhuman animals (zoophilia), and inanimate objects (fetishism); atypical activities include the infliction of pain or humiliation on another (sadism), experiencing pain or humiliation (masochism), and exposing one's genitals to unsuspecting strangers (exhibitionism). The most commonly observed paraphilias in clinical or correctional settings are those that involve illegal behavior if they are acted upon, such as pedophilia and the commission of sexual offenses against children, or nonconsensual sexual sadism and the commission of violent sexual offenses.

DSM-5 and the ICD

The DSM-5 lists the more commonly known paraphilias, including pedophilia, sadism, and fetishism; the paraphilias listed in ICD-10 are quite similar in content. For example, the ICD-10 defines pedophilia as "a sexual preference for children, usually of prepubertal or early pubertal age." DSM-5 retained the DSM-IV-TR criteria for Pedophilia (see Blanchard, 2013), which consider the duration and persistence of sexual interests, and adds a criterion about the age difference between the person and the child or children (the person is at least age 16 years and at least 5 years older than the child or children). Other paraphilias do not specify a minimum age requirement. An important change from DSM-IV-TR to DSM-5 is the distinction between paraphilias, which describe the atypical sexual interests, and paraphilic disorders, which require clinically significant distress or impairment.

Assessment

Interviews and questionnaires

Assessment requires a thorough sexual history, typically obtained through clinical interviews inquiring about sexual thoughts, interests, and behaviors, especially with regard to

atypical sexual targets or activities. Comprehensive interviews also can rule out explanations for atypical sexual thoughts, urges, fantasies, or behavior. For example, some individuals with obsessive-compulsive disorder (OCD) may report being disturbed by thoughts about molesting a child (Gordon, 2002). The differential diagnosis is made by determining if the thoughts are associated with sexual arousal or pleasure and by inquiring about symptoms of OCD.

Interviews can be very informative, but there are potential problems with recall and other biases in gathering self-report data on sexual interests or behavior (Wiederman, 2002). Questions about sexual history are sensitive and many interviewees may minimize or deny certain sexual interests or behaviors, especially those that are highly stigmatized, such as pedophilia. For example, Halpern *et al.* (2000) found that male adolescents were more willing to disclose criminal acts that they had committed than the fact that they had masturbated, although many of them had engaged in both behaviors. The validity of self-report may be increased if a rapport is established, which can occur after involvement in treatment (Worling & Curwen, 2000).

Questionnaires may reduce reluctance to disclose. Koss and Gidycz (1985) found that male respondents were more likely to admit engaging in sexually coercive behavior on a questionnaire than in an interview (see Daleiden *et al.*, 1998).

Other information

Sexual history information can sometimes be obtained from other sources, including interviews with an adolescent's sexual partner (if available) or a parent or guardian of children or younger adolescents (Skilling *et al.*, 2011). However, such information is usually limited. A review of clinical or criminal justice records can be very helpful. For example, clinicians can use information about sexual victim characteristics to make the diagnosis of pedophilia, because sexual arousal to children is more likely to be present among adolescent sex offenders who have very young victims, boy victims, and victims outside the offender's immediate family (Seto *et al.*, 2003). Sexual child victim characteristics can be summarized using the Screening Scale for Pedophilic Interests (SSPI), where having boy victims receives a score of 2, and having multiple child victims, victims under the age of 12, or unrelated child victims receive a score of 1 each. Thus, adolescent sex offenders with child victims can have a SSPI score ranging from 0 to 5. This information about previous sexual victims is also related to the risk of new sexual offenses (Seto *et al.*, 2004). Data on the sexual behavior problems of children can be collected from maternal observations through the Child Sexual Behavior Inventory (CSBI) (Friedrich, 1997). Childhood sexual behavior problems correlate with other problems on the CBCL.

Phallometry and viewing time

Phallometry involves the measurement of penile responses to sexual stimuli that systematically vary on the dimensions of interest, as developed by Freund (1963). Phallometric responses

are recorded as increases in either penile circumference or penile volume, providing a specific sexual measure, unlike other psychophysiological responses (Zuckerman, 1971). Phallometry discriminate various sexual behaviors, including sex offenses (Lalumière *et al.*, 2005; Seto, 2009), sadistic fantasies, and various other behaviors (Marshall *et al.*, 1991b; Freund *et al.*, 1996; Seto & Kuban, 1996; Seto *et al.*, 2012). For males who are not motivated to manipulate their phallometric responses, genital sexual arousal is substantially correlated with subjective sexual arousal (Chivers *et al.*, 2010).

Seto *et al.* (2000) evaluated the use of phallometric testing for adolescent sex offenders with child victims. Because an age-matched comparison group was not available, these adolescents were compared to young adults between the ages of 18 and 21 who had not committed sexual offenses involving children. As a group, adolescents with male victims had relatively higher responses to pictures of children than the young adult comparison participants. Adolescents with both male and female children as victims responded more to pictures of children than to pictures of adults (see also Rice *et al.*, 2012). Clift *et al.* (2009) found that phallometric test results predicted future reoffending among adolescent sex offenders, just as it does for adult sex offenders (Hanson & Morton-Bourgon, 2005).

Viewing time provides another objective measure, using various pictures. Adolescent or adult sex offenders with child victims can be distinguished from other men using such measures, although not all findings are consistent (Smith and Fischer, 1999; Abel *et al.*, 2004). Another potential problem is that subjects can explicitly manipulate their profile if they aware that viewing time is being monitored.

Associated psychopathology

Paraphilias and related sexual disorders often co-occur with mood and anxiety disorders (Kafka, 2003; Seto & Lalumière, 2010). However, longitudinal research is needed on the timing of these associations. Sexual behavior problems also co-occur with nonsexual behavior problems (Friedrich *et al.*, 2001), including attention deficit hyperactivity disorder, oppositional defiant disorder, or conduct disorder (Seto & Lalumière, 2010). France and Hudson (1993) reviewed studies on this topic and concluded that up to half of adolescent sex offenders would meet diagnostic criteria for conduct disorder.

Paraphilias can be comorbid, and engaging in one form of paraphilic behavior greatly increases the likelihood of engaging in another (Abel *et al.*, 1988; Zolondek *et al.*, 2001). Långström and Seto (2006) found exhibitionistic and voyeuristic behavior co-occurred more often than expected by chance in a nationally representative sample of young men between the ages of 18 and 21 from Sweden. There are limited co-occurrence data for adolescents.

Epidemiology

Prevalence and incidence

Neither the incidence nor the prevalence of paraphilias is known. Some limited evidence suggests that paraphilias are

relatively rare, although admitting or experiencing some paraphilic sexual interest is common (Briere & Runtz, 1989; Fromuth *et al.*, 1991; Templeman & Stinnett, 1991). Paraphilic interests have a lower threshold than paraphilias. As noted earlier, the DSM-5 makes a further distinction between paraphilias and paraphilic disorders, where the latter requires clinically significant distress or impairment for the diagnosis. Limited data are available in adolescents, although retrospective reports from adults suggest that sexual interests often begin to emerge following the onset of puberty (Seto, 2012). Most work uses clinical or correctional samples, usually on adults.

Risk factors

While many theories focus on the etiology, we focus on theories emphasizing conditioning or neurodevelopment, as these have the strongest support. We then discuss the theories' implications.

Conditioning

Masturbatory conditioning may influence risk for paraphilias (McGuire *et al.*, 1965; Laws & Marshall, 1990). Some individuals, for unspecified reasons, pair cues of unusual initial sexual experiences with the sexual pleasure elicited by these early experiences and learn to associate these cues with the powerful reinforcement of orgasm. There is equivocal relevant evidence, however, in humans. Rachman and Hodgson (1968) reported significantly increased sexual arousal to pictures of boots among normal volunteers in a set of frequently cited experimental studies examining the development of boot fetishism, but these studies did not have control conditions. Lalumière and Quinsey (1998) and Hoffmann *et al.* (2004) found a significant effect of conditioning on sexual arousal among male volunteers while Plaud and Martini (1999) reported mixed results in a conditioning study of nine male volunteers.

The efficacy of conditioning approaches for changing sexual arousal patterns has been reviewed elsewhere (Barbaree & Seto, 1997; Hoffmann, 2012). Overall, this research suggests that conditioning can have an effect on the suppression of sexual arousal of adolescent or adult sex offenders, but it is unclear how long these changes are maintained, what mechanisms are actually responsible for the changes in sexual arousal patterns, and whether the changes reflect an actual shift in sexual interests or greater voluntary control over sexual arousal when assessed in the laboratory (Mahoney & Strassberg, 1991; Lalumière & Earls, 1992).

Conditioning might play a role in maintaining rather than initiating paraphilic sexual arousal. For example, Dandescu and Wolfe (2003) found that atypical sexual fantasies preceded and accompanied the first sexual offence reported by a sample of 57 sex offenders with child victims; the sexual fantasies then increased in frequency after the first sexual offence. Approximately two-thirds of the offenders reported having any "deviant sexual fantasies" before their first contact with a child while 81% reported having such fantasies afterwards. This finding suggests that the sexual arousal and gratification experienced during the

first sexual offence increased the frequency of sexual fantasies among men who already had such fantasies.

Findings suggest that conditioning is unlikely to play a significant role in the onset of paraphilias. Experimental efforts to increase sexual arousal have produced small effects, but it is unclear how long conditioned changes in sexual responding can be maintained. If conditioning does play a role in the development of paraphilias, as suggested by Dandescu and Wolfe's study, then there is almost surely an interaction between conditioning experiences and other predisposing factors, such as a neurodevelopmental diathesis.

Neurodevelopment

Information on brain functioning can be obtained both directly and indirectly. Indirectly, investigators have compared cognitive function in sex offenders with child victims with other groups. Cantor *et al.* (2005) conducted a meta-analysis: For the adults, sex offenders scored lower on measures of intelligence than other offenders, who, in turn, scored lower than non-offending controls. For the adolescents, there was a significant difference between sex offenders and other offenders. Among the sex offenders, Cantor *et al.* found that intelligence scores appeared to be related to the proportion of the sample that was pedophilic, because sex offenders with child victims scored lower than sex offenders without any child victims. Moreover, there was a positive relationship between the age cut-off used to define child victims and mean intelligence score; in other words, samples composed of men who offended against younger children tended to produce lower mean IQ scores than samples composed of men who offended against older children.

In earlier studies, this same research group also found that pedophilic sex offenders were more likely to report experiencing head injuries before the age of age 13, but did not differ in reports of head injuries after age 13 (Blanchard *et al.*, 2002, 2003). The fact there was no difference in reports of head injuries after age 13 counters an alternative explanation that pedophiles have a retrospective reporting bias in recalling head injuries, because there would be no reason to think that head injuries before the age of 13 are more socially desirable than head injuries later in life. The fact that there was no difference after age 13 also suggests that there is a critical age window in terms of the impact of head injury on the development of pedophilia (and perhaps other paraphilias). This is an intriguing possibility because of other work suggesting that the time before and during puberty is critical in the development of sexual preferences in general. Of course, it is assumed that the relationship between head injury and pedophilia is causal. It is possible that a third variable explains both the higher incidence of head injury and pedophilia; for example, prenatal brain damage may increase accident-proneness, resulting in a higher risk for head injury as well as increase the likelihood that an individual will be pedophilic.

Researchers have also attempted to directly assess brain structure. Cantor *et al.* (2008) reported that pedophilic men had

less white matter than nonpedophilic men in the right superior occipitofrontal fasciculus and the right arcuate fasciculus. These white matter tracts connect areas that are involved in determining if a stimulus is sexually relevant, suggesting that pedophiles are somehow deficient in how they process and integrate sexual cues. Poepl *et al.* (2013) identified a number of gray matter volume differences between pedophilic sex offenders and controls, with differences in the orbitofrontal cortex and bilateral angular gyri correlated with aspects of sexual offending behavior such as age of child victims. Ponseti *et al.* (2012) were able to use fMRI activation changes in response to sexual stimuli to adults or children to distinguish pedophiles from controls with high accuracy.

Cycle of sexual abuse

Sexual abuse history may relate to adolescent sexual offending (Knight & Sims-Knight, 2003). Seto and Lalumière (2010) conducted a meta-analysis of studies that compared adolescent sex offenders and other adolescent offenders and found that adolescent sex offenders had more than five times the odds of having a history of sexual abuse. Difference was smaller for physical abuse history, and a similar pattern of results was found comparing adult sex offenders to other adult offenders (Jespersen *et al.*, 2009).

Adolescent sex offenders who have been sexually abused show relatively greater sexual arousal to children or coercive sex than those who have not been abused (Becker *et al.*, 1992; Hunter *et al.*, 1994). Among children, Friedrich *et al.* (2001) showed that scores on the CSBI could discriminate children who had been sexually abused from those who had not. Hall *et al.* (1998) found, in a sample of 99 sexually abused boys and girls between the ages of 3 and 7, that those who became sexually aroused during the sexual abuse were more likely to engage in sexual behavior problems involving others ($n = 62$) than those who did not ($n = 37$).

The sexually abused–sexual abuser hypothesis suggests that male children who are sexually abused are more likely to engage in sexual offending later in life. Burton (2003) described plausible mechanisms: modeling, conditioning, and changing of cognitions. In the Seto and Lalumière (2010) meta-analysis, adolescent sex offenders were also more likely to have been exposed to sexual violence in the family and had an earlier age of exposure to pornography or sex.

The mechanisms underlying the association between childhood sexual abuse and sexual behavior problems among children and adolescent sexual offending are not known. Possible important factors include aspects of abuse, such as duration or timing (Burton, 2003; Hunter *et al.*, 2003). There must be individual characteristics that increase both vulnerability to childhood sexual abuse and the likelihood of adolescent sexual offending, because many sexually abused children do not go on to commit sexual offenses, and many adolescent sex offenders have no known history of sexual abuse (Salter *et al.*, 2003).

Developmental trajectories

A developmental perspective is important because there are myriad differences between children, adolescents, and adults, and because there is both persistence and desistance in sexual offending across the lifespan. Retrospective studies suggest approximately half of adult sex offenders report that their first sexual offence was committed as a juvenile (Groth *et al.*, 1982) and up to half of adolescent sex offenders have engaged in sexual behavior problems under the age of 12 (Ryan *et al.*, 1996; Burton, 2000; Zolondek *et al.*, 2001). In prospective studies, however, only about 10–15% of adolescent sex offenders commit another sexual offence over 5 years (for reviews, see Caldwell, 2010). The proportion of children with sexual behavior problems who persist and commit a sexual offence as an adolescent is also low (Carpentier *et al.*, 2006). Taken together, these data indicate that many children with sexual behavior problems and many adolescent sex offenders desist. For many children, their sexual behavior problems may represent a reaction to sexual abuse that they have experienced, sexual precocity, or normative sexual play. For many adolescents, their sexual offenses may represent opportunistic and relatively transient antisocial behavior. A small group of children and adolescents, however, will persist in committing sexual offenses into adulthood. Adolescents who develop paraphilias such as pedophilia, exhibitionism, or voyeurism are more likely to persist in sexual offending pertaining to that paraphilia.

Of particular relevance is a study by Zolondek *et al.* (2001) of 485 adolescent males between the ages of 11 and 17, referred for assessment or treatment of paraphilic interests or behavior. The youths completed a questionnaire with questions about their sexual interests and experiences as part of their assessment. Twenty-six percent acknowledged engaging in fetishistic behavior, 17% acknowledged voyeuristic acts, and 12% acknowledged exhibitionistic behavior. The average age of onset across paraphilic behaviors was between 10 and 12, which is younger than the average age of onset found in retrospective studies (Abel *et al.*, 1987; Marshall *et al.*, 1991a). These data are consistent with the idea that the onset of paraphilias is around the time of puberty, just as many people are becoming aware of their sexual preference for males or females.

Treatment

Pharmacological

The common aim of pharmacotherapy for the treatment of pedophilia is to suppress sexual response involving children. These same medications have been used, to a lesser extent, in the pharmacological treatment of other paraphilias that can lead to much distress or impairment (e.g., nonconsensual sexual sadism). Much of the initial interest was in antiandrogens to reduce sexual response, but clinicians and researchers have more recently focused on serotonergic agents. Because of the impact of reducing androgens on physical development, anti androgens are very rarely, if ever, prescribed for minors, except in cases where the sexual behavior is highly dangerous

(e.g., very violent sexual assaults) and cannot be controlled by other means.

It is a logical hypothesis that anti androgens would have an impact on paraphilic sexual responses, because testosterone plays a critical role in male sexuality as well as aggression (Rubinow & Schmidt, 1996). The earliest clinical study was reported by Laschet and Laschet (1971), who treated more than 100 paraphilic men; most were pedophiles or exhibitionists. Cyproterone acetate (CPA) or medroxyprogesterone acetate (MPA) are among the most commonly prescribed agents, both of which interfere with the action of testosterone. The use of either drug in the treatment of paraphilias is off-label, meaning it is not specifically approved by regulatory bodies for this purpose. Side effects of antiandrogens include headaches, dizziness, nausea, gynecomastia, depression, and osteoporosis. As a result of these potentially serious side effects and the fact that some patients do not want to experience a massive reduction in their sex drive, treatment attrition and treatment compliance are major obstacles in antiandrogen treatment. For example, in Hucker *et al.* (1988), only 11 of 18 men completed the 12-week trial set out by the clinical investigators.

There is some support for the efficacy of antiandrogens in reducing the frequency or intensity of sexual urges and arousal, but there has been a dearth of larger, better-controlled outcome studies. Gijs and Gooren (1996) reviewed the literature evaluating the effects of CPA and MPA, focusing on methodologically stronger studies that included features such as random assignment, a placebo condition, and double-blinding (see also Thibaut *et al.*, 2010; Garcia *et al.*, 2013). Gijs and Gooren identified four controlled studies of CPA and six such studies of MPA. All four studies of CPA revealed that treated men had a significant reduction in sexual response while only one of the six MPA studies showed a significant difference between men in the treatment and comparison conditions.

Serotonin is involved in the regulation of human sexual behavior and anti depressant medications that have a serotonergic effect have long been known to reduce sexual desire and delay ejaculation in males (Meston & Gorzalka, 1992). The World Federation of Societies of Biological Psychiatry guidelines on the biological treatment of paraphilias are to consider psychotherapy first for adolescents exhibiting paraphilic symptoms, but to consider SSRIs for those who do not respond to psychotherapy alone, especially if the paraphilic symptoms are associated with OCD, impulse control disorders, or depression (Thibaut *et al.*, 2010). Unfortunately, the interest in serotonergic agents for the treatment of paraphilias appears to be almost entirely based on uncontrolled case studies or open trials (Gijs & Gooren, 1996); there has been only one experimental study that compared desipramine and chloripramine in a double-blind crossover trial that was preceded by a single-blind placebo condition (Kruesi *et al.*, 1992). Kruesi *et al.* reported a significant reduction of self-reported paraphilic behavior (predominantly exhibitionism, transvestic fetishism, telephone scatologia, and fetishism) with either drug,

but their result was difficult to interpret because only 8 of 15 paraphilic men completed the trial; four patients were dropped because they responded to the placebo, and three did not complete the drug trial. Including the patients who responded to placebo would have attenuated, and perhaps eliminated, the apparent effect of the drugs on self-reported paraphilic behavior.

Despite the intuitive appeal of pharmacological interventions to reduce sexual drive and thus the likelihood of (illegal) paraphilic behavior, reviews of outcome studies suggest that there is no strong empirical support for the idea that such interventions can reduce sexual recidivism.

Psychosocial interventions

Aversive conditioning techniques were used as early as the 1950s for paraphilic interests such as fetishism and transvestic fetishism (e.g., Raymond, 1956; Marks & Gelder, 1967). In the behavioral treatment of paraphilias, aversion techniques are used to suppress sexual arousal to the atypical target or activity, while masturbatory reconditioning techniques are used to increase sexual arousal to acceptable targets (peers or adults) and activities (consenting sexual activities). In aversion procedures, unpleasant stimuli, such as mild electric shock or the odor of ammonia, are paired with repeated presentations of sexual stimuli depicting the paraphilic target or activity. In a variation called covert sensitization, the aversive stimulus is imagined, for example, being discovered by family, friends, or coworkers while engaging in paraphilic behavior. Overall, the existing research suggests that behavioral techniques can have an effect on sexual arousal patterns, but it is unclear how long these changes are maintained and whether they result in actual changes in interests, as opposed to greater voluntary control over pedophilic sexual arousal (Lalumière & Earls, 1992; see also Hoffmann, 2012).

Cognitive-behavioral treatments aim to teach individuals how to manage their sexual urges, often as part of a more comprehensive program to address clinical needs (see Pullman & Seto, 2012). Published evaluations have reported promising results. Carpentier *et al.* (2006) reported on a long-term evaluation of 135 children with sexual behavior problems, compared to 156 children from the same outpatient clinic. The children with sexual behavior problems were randomly assigned to a play therapy group or a cognitive-behavioral treatment (CBT) group. Both treatments were manualized and ran for 12 hour-long sessions. The CBT group was highly structured and focused on education and behavior management. The play therapy group was less structured and more reflective, although it focused on many of the same themes: sexual behavior problems, boundaries, parenting skills, and sex education. Children assigned to the CBT group were significantly less likely than children assigned to the play therapy group to sexually offend (defined as an arrest for a sexual offence or a child welfare report of sexual abuse perpetration) during the 10-year follow-up period. In fact, the rate of sexual offending among children in the CBT group was not

significantly different from the comparison group without any sexual behavior problems.

Borduin *et al.* (1990) reported a significant effect of treatment in a small sample of adolescent sex offenders, using a multisystemic treatment that targeted factors associated with criminal behavior, including antisocial attitudes and beliefs, associations with antisocial peers, and substance abuse (Andrews & Bonta, 2010). This multisystemic treatment is distinguished by being skills-focused, involving both the adolescent and his family, and paying careful attention to program fidelity and individualization. Multiple studies have shown that multisystemic treatment can significantly reduce recidivism and other negative outcomes among serious adolescent offenders (Henggeler *et al.*, 1998). Borduin and Schaeffer (2001) extended the Borduin *et al.* study by showing that this multisystemic treatment had a large impact on sexual recidivism in a larger sample of 48 juvenile sex offenders although it was not designed specifically for this group. More recent treatment outcome studies show that, compared with typical community-based services provided to adolescent sex offenders, multisystemic therapy resulted in greater reductions in sexual behavior problems, criminal behavior, and substance use (Borduin *et al.*, 2009; Letourneau *et al.*, 2009). See also Chapter 49 (Young and Church, this edition).

Summary and conclusions

There are many unanswered questions about the onset, development, and prognosis of paraphilias. Relatively little research has been conducted on adolescents, perhaps reflecting a discomfort with the idea that some adolescents and older children engage in problematic sexual behavior as a result of atypical sexual interests that are very likely to be stable over their lifetimes (Seto, 2012). As a result, this section has drawn upon relevant studies of adult sex offenders. This is not to suggest that children with sexual behavior problems or adolescent sex offenders are likely to have paraphilias. In fact, it is likely that most do not, given the high rate of desistance in sexual behavior problems from childhood to adolescence and in sexual offending from adolescence to adulthood. However, a small minority of children and adolescents do persist and are likely to continue engaging in criminal sexual behavior without effective intervention.

Moreover, most of the research summarized in this chapter pertains to pedophilia, with some additional studies on paraphilias such as sexual sadism, exhibitionism, and voyeurism. Much more empirical work is needed to understand the commonalities and differences across different paraphilias. It may be the case, for example, that the etiological factors behind activity paraphilias may differ from those for target paraphilias. There is emerging evidence to support the idea that there are neurological risk factors for pedophilia. Given the comorbidity of paraphilias, it is possible that other paraphilias are also influenced by common neurological factors. The work of Cantor and colleagues have identified a number of indicators

of neurological perturbations—non-right-handedness, lower IQ, lower scores on other measures of neuropsychological functioning, and decreased white matter in two major tracts—that suggest paraphilias have a prenatal origin (Cantor *et al.*, 2008; see also Seto, 2009, 2012; Poepl *et al.*, 2013). Or, it is possible that the predisposition to developing paraphilias is influenced prenatally, and the expression of paraphilias is influenced by subsequent experiences, as in the robust association between childhood sexual abuse and sexual offending involving children (Jespersen *et al.*, 2009; Seto & Lalumière, 2010).

As is true for many other disorders, we know more about the assessment than the treatment of paraphilias. Further research on paraphilias will be expedited by the development of age-appropriate measures of sexual interests. Viewing time is a particularly promising technology. Unlike the adult literature, however, there are some promising results in the treatment of sexual behavior problems in children and sexual offending among adolescents. These treatments share a common focus on skills, behavior, problem-solving, and involve parents or other caregivers. Further advances in treatment will benefit from a greater understanding of the etiology and developmental course of paraphilias.

CHAPTER 70

Sleep interventions: a developmental perspective

Allison G. Harvey¹ and Eleanor L. McGlinchey^{1,2}

¹Department of Psychology, University of California, Berkeley, CA, USA

²New York State Psychiatric Institute, Columbia University Medical Center, NY, USA

Introduction

In this chapter, we review evidence that we believe points to sleep disturbance as contributing in several ways to core problems and symptoms of children and youth. We highlight that treatments targeting sleep represent unique opportunities for intervention that have potential for a broad range of positive outcomes.

Basic overview of human sleep architecture across development

Beginning in infancy, the brain cycles through stages of neural activity that correspond to periods of wakefulness and different stages of sleep. “Mature” sleep is divided into two major categories: rapid eye movement (REM) sleep and non-REM (NREM) sleep. NREM sleep is subdivided into four stages: Stage 1 occurs at transitions of sleep and wakefulness; Stage 2 is characterized by frequent bursts of rhythmic electroencephalography (EEG) activity, called sleep spindles, and high-voltage slow spikes, called K-complexes; Stages 3 and 4 (also called slow wave sleep or delta sleep), represent the deepest stages of sleep and are comprised largely of high-voltage EEG activity in the slowest (delta) frequency range. In newborn infants, each sleep cycle is around 60 min, with 50% in “active sleep” and 50% in “quiet sleep.” Active sleep is similar to REM sleep in adults and involves head movements, rapid eye movements, fast and irregular respiration, and increased heart rate. Quiet sleep is similar to NREM sleep in adults and involves few movements. By about 2 years of age, active sleep declines to 20–25% and slow wave sleep is maximal, making it difficult to wake a child during the first sleep cycle. By 6–11 years of age clearer cycles of sleep, each about 90 min, emerge such that the amount of Stages 3 and 4 sleep and REM reduces and Stage 2 sleep increases. By around 11 years of age slow wave sleep is at 40% and continues to decline across adolescence, which is thought to parallel pruning of cortical density. By mid-adolescence sleep conforms to the 90-min cycle of adults. REM sleep is retained across

childhood, adolescence, adulthood, and older adults whereas slow wave sleep decreases across the age range (Carskadon & Dement, 2011).

Conceptual models

A convergence of processes work together to support sleep. The conceptual models briefly reviewed in this section were selected as they highlight several major contributors.

Two-process model

Two independent regulatory processes interact to regulate the timing, intensity, and duration of sleep: a homeostatic sleep process and a circadian sleep process (Borbély, 1982). The first, often called “Process S,” represents a sleep–wake dependent homeostatic component of sleep that increases as a function of previous wakefulness and gradually decreases over the course of a sleep period. The second process, often called “Process C,” is the circadian component, which arises from the endogenous pacemaker in the suprachiasmatic nuclei (SCN). At the molecular level, intrinsically rhythmic cells within the SCN generate rhythmicity via circadian genes. The process by which the pacemaker is set to a 24-hour period and kept in appropriate phase with seasonally shifting day length is called entrainment, which occurs via zeitgebers (“time giver” in German). In other words, the sleep and circadian systems are open systems, readily open to influence from the environment. The primary zeitgeber is the daily alteration of light and dark. The SCN is also responsive to nonphotic cues such as arousal/locomotor activity, social cues, feeding, sleep deprivation, and temperature (Mistlberger *et al.*, 2000). Hence, there is a clear biological pathway by which behavioral changes in terms of the timing exposure to light and regularizing activities, meal times etc. that form the basis for intervention. Note that the SCN is not fully developed at birth. Hence, while the newborn infant is sensitive to zeitgebers, greater sensitivity will emerge across the first year of life.

Safety/vigilance/arousal

Sleep is naturally restricted to safe times and places (e.g., animals tend to sleep in safe burrows or nests that minimize dangers). This system has adaptive advantages (inhibiting sleep when we are in danger) but also has costs. Sleep and vigilance represent opponent processes since sleep is in essence a turning off of awareness and responsiveness to the external environment (Dahl & Lewin, 2002). Hence, it is natural that states of vigilance and anxiety are antithetical to going to sleep. Children can experience fear as well as other sources of cognitive or emotional arousal that prevents an overall sense of safety and is likely to be antithetical to sleep. Adolescents can get into the habit of mentally reviewing or replaying worrisome thoughts and/or memories of stressful events. Some youth with stressful memories or specific fears manage to avoid these during the day through distracting activities, but at night—especially when trying to fall asleep—the lack of distracters can result in rumination on these thoughts.

Three-P model

The three-P (3P) model (Spielman *et al.*, 1987), also referred to as the three-factor or the Spielman model, is a useful heuristic to guide assessment and treatment of sleep problems. The three-P model is a diathesis-stress model which includes predisposing, precipitating, and perpetuating factors. The predisposing factors can be biological (e.g., regularly elevated cortisol), psychological (e.g., tendency to worry) or social (e.g., school schedule incompatible with sleep schedule). Precipitating factors, such as stressful life events, then trigger the acute onset of sleep problems. Perpetuating factors, such as maladaptive coping skills or an extension of time in bed, can then contribute to the acute sleep problem developing into a chronic or longer term disorder. Within this framework, predisposing factors represent a constant vulnerability for sleeping problems. Precipitating factors trigger the acute sleep problem, but the influence of these factors diminishes over time. By contrast, perpetuating factors then come into play and serve to maintain the sleep problems. As a result, the perpetuating factors are typically the targets of treatment.

Brain development

Highly relevant to teenagers is the temporal gap between the development of brain regions involved in behavior regulation and cognitive control functions (prefrontal cortex; PFC) and the brain regions controlling emotional processing and behaviors associated with reward/punishment (ventral-medial areas of the PFC) that have bidirectional connections with the amygdala and the hypothalamus (Giedd *et al.*, 1999; Quevedo *et al.*, 2009; Silk *et al.*, 2009; Steinberg, 2010). Importantly, these same prefrontal and inter-related limbic regions also appear to be those networks known to display the greatest sensitivity to insufficient sleep (Yoo *et al.*, 2007).

Consequences of poor sleep

Sleep and sleep disturbance have pervasive effects, particularly across development.

Sleep is critical for affect regulation

There is robust evidence in adults that sleep deprivation undermines emotion responding and regulation the following day (Pilcher & Huffcutt, 1996; Yoo *et al.*, 2007) with similar findings among youth (Talbot *et al.*, 2010; McGlinchey *et al.*, 2011). Studies experimentally restricting sleep in healthy youth have reported decrements in affective functioning as a function of sleep loss (Leotta *et al.*, 1997; Talbot *et al.*, 2010; McGlinchey *et al.*, 2011). Conversely, better quality sleep may buffer against affective risk. For example, a prospective study of children at high risk for major depressive disorder found that a greater percentage of slow wave sleep during childhood was protective against the development of depression during adolescence and young adulthood (Silk *et al.*, 2007). Interestingly, a study by Zohar *et al.* (2005) suggests that the context in which the emotion is experienced is important for determining the valence (positive versus negative) of the emotion experienced under conditions of sleep deprivation.

Sleep is important for cognitive functioning

It seems plausible that sleep disturbance may impair cognitive functioning in children given that adverse and severe effects of sleep deprivation on cognitive functioning have been clearly demonstrated in adults (Van Dongen *et al.*, 2003). In particular, there are at least two stages of memory where sleep has been demonstrated to be important. Yoo *et al.* (2007) have presented evidence for a critical role for sleep before learning in preparing key neural structures for efficient next-day memory encoding. Specifically, sleep-deprived participants exhibit a large 40% reduction in the ability to form new human memories under conditions of sleep deprivation (Walker & Stickgold, 2006). In contrast to the impairment of memory encoding following sleep loss, recent findings have characterized the proactive benefit of sleep on memory encoding. Interestingly, a daytime nap restores the normal deterioration in learning capacity that develops across the day (Mander *et al.*, 2011). In addition, sleep obtained after learning also plays a critical role in the consolidation of episodic (fact-based) declarative memories. Sleep deprivation after learning prevents the consolidation of new memories (both emotional and nonemotional). Moreover, experimentally enhancing the quality of sleep, specifically slow wave sleep (Stages 3 and 4), causally enhances consolidation and hence long-term retention of [nonemotional] memories (Stickgold & Walker, 2005; Payne *et al.*, 2009; Diekelmann & Born, 2010). Beyond simply strengthening individual fact-based memories, sleep after learning also appears to help integrate newly learned information.

Although this compelling evidence has accrued based on adults, the developmental implications have attracted considerable attention. Consistently, an observation of 135 healthy school children (Sadeh *et al.*, 2002) as well as a comparison of 1 hour of restricted versus extended sleep in 77 children (Sadeh *et al.*, 2003) showed clear adverse consequences of inadequate sleep on cognitive functioning. In addition to the acute effects

of sleep loss, cognitive impairments may persist over time. In one prospective study, parent-reported sleep problems during childhood significantly predicted neuropsychological functioning in early adolescence (Gregory *et al.*, 2009). Adverse effects in this domain are likely to be particularly critical for children given that educational achievements (so reliant on cognitive function) will have far reaching and long-term consequences. For example, a meta-analysis of 60 studies of the association between school performance and sleep quality, total sleep time and daytime sleepiness indicated modest but significant associations (Dewald *et al.*, 2010). In another meta-analysis of healthy school-age children (5–12 years old) across 86 studies and 35,936 children, sleep duration was clearly associated with cognitive performance, particularly executive functioning, on tasks that address multiple cognitive domains and with school performance, although not with intelligence, sustained attention or memory (Astill *et al.*, 2012).

Sleep is important for health and contributes to obesity

Sleep deprivation increases appetite, weight gain, and insulin tolerance (Spiegel *et al.*, 2004). Indeed, in a meta-analysis involving 30 studies (12 in children) and 634,511 participants, an association between short sleep and obesity was observed across the age range. Specifically, there was a 60–80% increase in the odds of being a short sleeper among children who were obese (Cappuccio *et al.*, 2008). Furthermore, experimentally induced short-term sleep deprivation in normal weight college-age volunteers is associated with disturbed appetite hormones (ghrelin and leptin) in a direction associated with obesity (Spiegel *et al.*, 2004). The mechanisms of these effects are related to ghrelin and leptin, which regulate energy balance in the body. Leptin levels are lower under conditions of sleep deprivation. Under conditions of normal sleep, leptin reduces in response to calorie shortage and is associated with hunger and increase in response to calorie surplus. Ghrelin levels are higher under conditions of sleep deprivation. Under normal sleep conditions, higher levels are associated with increased appetite.

Sleep deprivation is associated with behavioral problems including substance use

From pre-schoolers right up through the childhood and adolescent years, multiple reports indicate an association between inadequate sleep and behavioral problems (Sadeh *et al.*, 2002; Bates *et al.*, 2003). Indeed, in the Astill *et al.* (2012) meta-analysis described earlier, shorter sleep duration was associated with more behavioral problems and both internalizing and externalizing behavioral problems.

In terms of substance use problems in a Finnish sample of adolescents, irregular sleep schedules and daytime sleepiness accounted for 26% of the variance in substance use in 15-year-old boys and 12% in 15-year-old girls (Tynjala *et al.*, 1997). Another large study of 4500 12–17-year-olds found that adolescents who had trouble sleeping reported greater use of alcohol (odds ratio of 2.6), marijuana (odds ratio of 2.4) and

cigarettes (odds ratio of 2.2) (Johnson *et al.*, 1999). It is possible that the effects of drugs and alcohol may be sought out for the sedation and/or emotional regulatory effects or for rewarding and/or stimulating effects. In addition, sleep disturbance could also represent a direct effect of use of certain substances.

Sleep deprivation contributes to suicidality

Teens with more insomnia and nightmares reported more suicidal ideation (Choquet & Menke, 1989) and insomnia and hypersomnia were independently associated with suicidal ideation (Choquet *et al.*, 1993). Poor sleep has also been associated with suicide attempts. Eighty one percent of teens presenting to an emergency room following a suicide attempt reported difficulty falling asleep or early morning waking immediately preceding the attempt. Nightmares were associated with increased risk for suicide attempts and those who slept less than 8 hour were 3 times more likely to attempt suicide (Liu & Buysse, 2006). Poor sleep has also been associated with suicide completion. Insomnia also predicts adolescent hospitalization for suicide attempt (Gasquet & Choquet, 1994).

Using a psychological autopsy protocol in which parents, siblings, and friends were interviewed between 4 and 6 months after the suicide, Goldstein *et al.* (2008) compared adolescent suicide completers ($n = 140$) with an age/sex matched control group ($n = 131$). Suicide completers had higher rates of overall sleep disturbance, insomnia, and hypersomnia within the past week.

Epidemiology

Reported bedtime is delayed and sleep duration decreases with increasing age (Liu *et al.*, 2005). Sleep problems, as reported by parents, range from 20% to 30% (e.g., Lozoff *et al.*, 1985; Mindell, 1996; Anders & Eiben, 1997; Mindell, 1999; Stores, 2006). Among older children, there can be a discrepancy between parent and child report of sleep problems (in both directions). Most of the epidemiological work in this area draws from samples collected in the United States or Europe. Interestingly, one study compared children in grades 1–4 in the United States and in China. Chinese children went to bed approximately half an hour later (9:02 vs 8:27 PM) and woke up half an hour earlier (6:28 vs 6:55 AM), resulting in an average sleep duration that was 1 hour less (9.25 vs 10.15 hours) (Liu *et al.*, 2005). Cultural differences in sleep are an understudied topic.

Longitudinal outcome and sleep as a risk factor

Untreated sleep problems first presenting in infancy are known to persist during school-aged years and often become chronic (Zuckerman *et al.*, 1987; Pollock, 1994). Evidence has steadily accrued indicating that insomnia is an independent risk factor

for first and recurrent episodes of depression. For example, community residing youth ($N = 4500$) who reported frequent trouble sleeping were more likely than normal-sleeping controls to report anxiety or depression (odds ratio = 22.7) (Johnson *et al.*, 1999). A similar study of 1014 teens found that chronologically primary insomnia significantly predicted future depression (hazard rate = 3.8) but that primary depression did not predict subsequent insomnia (Johnson *et al.*, 2006). Insomnia symptoms predicted subsequent depression in another large adolescent community panel (Roberts *et al.*, 2002); elevated insomnia at Wave 1 predicted greater depression severity at Wave 2 even when controlling for Wave 2 insomnia. Moreover, there is substantial evidence that sleep problems emerging during early childhood are independently predictive for the later onset of depression (Gregory *et al.*, 2005; Ong *et al.*, 2006). Among 1760 high school students aged 16–18, Danielsson *et al.* (2012) replicated the finding that sleep disturbances predict depressive symptoms 1 year later. The novel contribution of this study is that catastrophic worry partially mediated the relationship. While girls reported more sleep disturbances, depressive symptoms, and catastrophic worry relative to boys, the results were similar regardless of gender. The tendency toward catastrophic worry is treatable, a point to which we will return.

In a study of early-onset bipolar disorder ($n = 82$), sleep disturbance was reported by about half of the parents as one of the earliest symptoms observed (Faedda *et al.*, 2004). In another study, sleep disturbances (and anxiety disorders) were identified as an antecedent to the onset of bipolar disorder in a subset of high-risk youth (Duffy *et al.*, 2007). Further evidence is provided by findings reported in a study (Shaw *et al.*, 2005) of 100 at-risk children with a parent with Bipolar I as well as a control group of 112 children with well parents. Decreased sleep was one of the distinguishing features of the high-risk group.

Two large prospective studies with nonclinical adolescent samples in the United States provide evidence that insufficient sleep predicts worse mental health at follow-up, after controlling for baseline levels of functioning (Roberts *et al.*, 2002; Fredriksen *et al.*, 2004). A long-term longitudinal study of the sons of alcohol-dependent men found that insufficient sleep and overtiredness among children of ages 3–5 were predictive of early use of alcohol, cigarettes, and other drugs in early adolescence, after controlling for parents' alcoholism (Wong *et al.*, 2009). These findings for boys were replicated in a community sample (Wong *et al.*, 2010). Recent research using data from the National Longitudinal Study of Adolescent Health suggest that insufficient sleep leads to drug use among teens, and that patterns of sleep and drug use are spread via social networks (Mednick *et al.*, 2010). These social network analyses suggest that insufficient sleep mediates the relationship between adolescents' own drug use and the drug use of their friends.

Additional longitudinal research focused on elucidating risk factors seems like a good investment of research effort given that it is so commonly observed that symptoms of various problems

experienced by children are worse during periods of inadequate sleep.

Assessment

A thorough assessment of a young patient would typically involve the seven parts listed in Table 70.1. We will focus on the first part—the assessment of past and current sleep. The evaluation of sleep problems should take place within two general frameworks: (i) the 3P model that helps organize material into predisposing, precipitating, and perpetuating factors (see Section “Three-P model”) and (ii) the context (considering stage of development, social situation, and culture).

A widely held assumption is that a sleep problem is always secondary to, or an epiphenomenon of, the so-called “primary” psychiatric disorder. Consequently, complaints of sleep problems have tended to be dismissed or regarded as trivial by both patients and their caregivers or, at most, seen as a by-product of the coexisting disorder. By contrast, evidence is accruing to indicate that sleep problems can be important but under recognized contributors to the multifactorial cause and maintenance of several comorbid problems, such as those reviewed earlier in this chapter. Hence, when a sleep problem is present, it should be targeted in treatment and not assumed to remit with treatment of the comorbid condition. The value of this approach is illustrated by studies comparing depressed patients who are treated only for their depression (with an antidepressant) versus depressed patients who are treated for both the depression (with an antidepressant) and insomnia (with cognitive behavior therapy). The combined approach was superior for both depression and insomnia outcomes (Manber *et al.*, 2007). Although this study was conducted with adults, it is very tempting to speculate that similar findings would emerge in studies of youth.

The goal of the assessment is to establish a diagnosis and a formulation and to obtain sufficient information to devise

Table 70.1 Assessment of sleep problems: domains to include.

1	A sleep assessment, current, past. Orient to sleep diary
2	A review of medical history, including hospitalizations, current medications, past and current medical conditions, and so on
3	A developmental assessment, including school functioning, developmental disabilities, prematurity, and so on
4	A family history of sleep disorders
5	A psychosocial history, including cultural context, impact on family, life events, and so on
6	A behavioral and psychiatric assessment because sleep problems often co-occur with other diagnoses such as depression, anxiety, ADHD, and so on
7	A physical exam, including growth check, appearance, nose/throat/mouth (possible risk factors for sleep-related breathing problems), neurologic exam, and so on

Source: Based on Mindell and Owens (2009).

a treatment plan. The latter involves unraveling the chain of factors that contribute to the sleep disturbance. Ideally, we suggest obtaining information via a multi-method approach that includes the methods discussed in Sections “Clinical interview, Questionnaires, Sleep diary, Polysomnography (PSG), and Actigraphy.” If the context allows, ideally the assessment should begin before the first visit. It can be expedient and helpful to send some of the questionnaires, as well as the sleep diary, to be completed before the first meeting.

Clinical interview

As we have outlined elsewhere (Harvey & Spielman, 2011), a dual approach to assessment is suggested that uses a “wide lens” to establish the broad thematic structure of the problem (e.g., what part of the night is disturbed, daytime activities that affect sleep, thoughts about sleep, worries about the daytime functional deficits, sleep–wake habits, etc.). The other approach is pointedly personal and uses a “focused lens” that dissects a particular night on which difficulty sleeping was experienced—and the subsequent day.

Attention needs to be paid in the evaluation to comorbid conditions such as psychiatric, sleep, and medical disorders. Consistent with the consensus of the field, it is assumed that these disorders may trigger, contribute to, or be unrelated to the sleep problem.

One common vulnerability factor has been associated with child temperament; namely, children who are known to be difficult to calm are least likely to fall asleep or stay asleep without the assistance of a caregiver. Additional factors that may perpetuate sleep problems in young children include caregiver attributes including symptoms of depression (Gress-Smith *et al.*, 2012) and parental work schedule (Sinai & Tikotzky, 2012). Recent research also suggests that when the parental expectations for sleep behavior do not match the typical development of childhood sleep habits, poor sleep among young children is common (Tikotzky & Sadeh, 2009). Finally, there are environmental factors that may exacerbate problems that the child has with falling asleep or also with parental difficulties in setting clear limits for bedtime (Mindell *et al.*, 2006).

Questionnaires

The Sleep Habits Survey (Owens *et al.*, 2010a; Wolfson & Carskadon, 1998) comprises 20 items each rated on a 4-point scale. Child and parent versions are available (Gruber *et al.*, 1997). Both have good psychometrics (Sadeh *et al.*, 2000). This measure includes a measure of sleepiness (e.g., sleepiness while studying, in class, conversing, etc.) and the Children’s Morningness–Eveningness Preferences (CMEP) Scale which is a 10-item measure of eveningness adapted by Carskadon *et al.* (1993). Scores range from 10 (Extreme evening preference) to 42 (extreme morning preference). The Brief Infant Sleep Questionnaire has nine items, validated for 5–29-month year olds and assesses sleep duration, night waking, nocturnal wakefulness, and sleep onset time (Sadeh, 2004). The Pediatric Sleep

Questionnaire contains 22 items and has been validated for 2–18-year-olds. It includes three subscales: snoring, sleepiness, and behavior (Chervin *et al.*, 2000).

Sleep diary

The sleep diary is perhaps the most helpful tool for assessing the current sleep problem. There are several options available. The need for a standard sleep diary has been recognized and is being addressed by a work group of experts (Carney *et al.*, 2012). The completion of a paper version is inexpensive and easy to use but increasingly web-based and electronic options are available which can increase efficiency and accuracy (because the data are time stamped, ensuring that the diary really is completed each morning). The enhanced awareness arising from self-monitoring can have a therapeutic effect.

It is helpful to ask the patient to continue to complete the diary across the course of treatment as a means of monitoring progress and adjusting treatment recommendations. Keep in mind that the diary questions can be individualized on the basis of issues discovered during the clinical assessment that are to be targeted in treatment (e.g., for some young people, adding questions about daytime energy level can be helpful). Parents can be recruited to assist with the completion of the diary among older children and can be the main completer for younger children.

Polysomnography (PSG)

Polysomnography, also known as a sleep study, is used to classify sleep into stages. It involves placing surface electrodes on the scalp and face to measure electrical brain activity (electroencephalogram), eye movement (electrooculogram), and muscle tone (electromyogram). The data obtained are used to classify each epoch of data by sleep stage and in terms of sleep cycles (NREM and REM).

PSG is important for diagnosing periodic limb movement disorder (PLMD) and obstructive sleep apnea and other sleep-related breathing disorders (SBDs). The evidence for the use of PSG to diagnose sleep disorders in children has been subject to detailed review (Aurora *et al.*, 2012). Standard recommendations for PSG use in children with suspected sleep-related breathing disorders include PSG as a necessary assessment tool for the diagnosis of obstructive sleep apnea syndrome (OSAS) and as a pre- and post-operative assessment for residual OSAS following an adenotonsillectomy (Aurora *et al.*, 2012). PSG is indicated for positive airway pressure (PAP) titration in children requiring this treatment for nighttime apnea episodes. Standards also require the use of PSG in diagnosing PLMD and narcolepsy in children (Aurora *et al.*, 2012). Additionally, standards indicate that the multiple sleep latency test (MSLT) (Littner *et al.*, 2005) should be used to assess the degree of excessive daytime sleepiness associated with the diagnosis of narcolepsy among children. Additional guidelines and options are reviewed in the two studies that may be used alongside the clinical judgment of a child sleep specialist.

As the diagnosis of insomnia relies solely on a subjective complaint, PSG is not needed nor recommended for the standard evaluation of insomnia (Reite *et al.*, 1995). However, it should be conducted for patients who do not respond to standard insomnia treatment. In the latter case a comorbid sleep disorder may be present but covert. Major limitations of PSG include the expense and discomfort. Hence, PSG is typically only conducted for one to two nights.

Actigraphy

An alternative objective assessment of sleep is the use of actigraphy. Actigraphy has increasingly been employed in an attempt to overcome shortcomings associated with PSG. Actigraphs are wrist watch-like devices that provide an estimate of the sleep/wake cycle via movement detectors (accelerometers). Within is a sensor, a processor and sufficient memory to record for up to several weeks. The processor samples physical motion and translates it to digital data. It summarizes the frequency of physical motions into epochs of specified time duration and stores the summary in memory. These data are then downloaded and automatic scoring methods (algorithms) are used to derive levels of activity/inactivity and generate various sleep/wake parameters. Relative to PSG, actigraphy is considerably less expensive and less intrusive and it provides the opportunity to continuously monitor patients over long time periods in their normal environment. According to two comprehensive reviews by the American Sleep Disorders Association (Sadeh *et al.*, 1995; Ancoli-Israel *et al.*, 2003), actigraphy is considered to be a useful and acceptable instrument to measure sleep–wake schedule and sleep quality. Furthermore, actigraphy is appropriate for examining sleep variability (i.e., night-to-night variability). Although there is considerable data validating actigraphy in adult normal sleepers, data testing the validity of actigraphy for infants, children, and youth is lacking. Moreover, it is important to note that the type of watch and the scoring algorithm used can result in substantial scoring differences.

Classification

Various diagnostic systems offer criteria for sleep disorders including the International Classification of Sleep Disorders' (ICSD) criteria (American Academy of Sleep Medicine, 2014), the Diagnostic and Statistical Manual of Mental Disorders' (DSM-5) criteria (American Psychiatric Association, 2013) and the International Classification of Diseases (ICD) (World Health Organization, 1992). Unfortunately these offer relatively few specific adaptations to diagnose sleep problems in children and youth and there are many differences across the three offerings. Hence, rather than delve into the complexities here, as we move on to discuss treatment, we have focused on the disorders that are common across the three systems and most commonly experienced by children and adolescents.

Interventions for common sleep disorders of childhood and adolescence

As will become evident across this section, there is a great need for treatment research. The early results for behavioral interventions are particularly promising. Although these have not been tested specifically for various comorbidities (e.g., autism, bipolar disorder, ADHD, etc.), the data on using these approaches for sleep disturbance comorbid with another psychiatric or medical problems in adults are very encouraging (Smith *et al.*, 2005), albeit with some potential adaptations in certain situations (Harvey, 2009). The data on behavioral interventions for sleep problems in young people are also very promising. There are several advantages to treating sleep problems nonpharmacologically including that behavioral interventions are: safe (few side effects and no potential for causing adverse interactions with prescribed medications), simple (easy to do), and inexpensive (especially considering that the positive effects have been shown to endure even up to 24 months in adults trials).

Problems going to sleep and staying asleep in young children

Bedtime struggles and middle of the night wakings are not only a source of sleep disruption for children and their parents but also can be a source of conflict and negative emotion among family members, contributing to negative parent–child interactions and marital discord. One aspect of the difficulty is that young children often show a “paradoxical” reaction when obtaining insufficient or inadequate sleep. That is, sleep-deprived young children (whether from insufficient or disrupted sleep) often look irritable, impulsive, with some symptoms of distractibility and emotional lability, and may appear overly active.

Interventions for bedtime problems and night wakings are founded on principles of learning and behavior (e.g., reinforcement, extinction, and shaping). Treatments involve training parents with a therapist guiding interventions on how to change their child's problematic sleep habits or sleep-related behaviors. The different behavioral interventions for early childhood sleep difficulties, and the level of empirical support for each, have been reviewed in a recent practice parameters paper commissioned by the American Association for Sleep Medicine (Mindell *et al.*, 2006). The first of these interventions is “unmodified extinction” and involves having the parents put the child to bed at a designated bedtime and then ignoring any crying, tantruming, or calling out by the child until a set time the next morning (although parents monitor for illness, injury, etc.). The effective use of extinction requires parental consistency. No matter how long the crying lasts, parents must ignore this every night. Otherwise, the child will only learn to cry longer the next time. The common term used in the media and self-help books to describe unmodified extinction techniques is the “cry it out” approach (Ferber, 1985). The difficulty with the use of

unmodified extinction procedures is that it is often perceived as stressful by parents and many are not able to ignore the crying long enough for the procedure to be effective. An alternative to unmodified extinction is extinction with parental presence. In this variant, the parent stays in the child's room at bedtime but ignores the child and his/her problematic behavior. For some parents this procedure helps them to be more consistent and is more acceptable to them.

Another intervention based on extinction principals is "Graduated Extinction." Parents are instructed to ignore bedtime crying and tantrums on a specified schedule of check-ins. The period between check-ins is often tailored with the guidance of a therapist with considerations for the child's age, temperament, and the parents' judgment of how long they can tolerate the child's crying. Parents can also choose to check on their child on a fixed schedule (e.g., every 5 minutes) or with incrementally longer intervals (e.g., 5, 10, then 15 min). When using incrementally longer intervals, increases across successive checks within the same night or across successive nights can gradually reduce to no check-ins. Parents should only comfort their child for a brief period and no longer than a minute. Through the use of Graduated Extinction, the child will develop "self-soothing" skills so that he/she falls asleep independently without the parent. In self-help books, this type of intervention is often referred to as "sleep training." (Mindell, 2005).

Behavioral interventions can also include powerful methods for increasing homeostatic drive to sleep, such as developmental adaptations of stimulus control and sleep restriction (described in Table 70.2) which involve a small amount of sleep restriction that builds the homeostatic process.

Positive Routines is an intervention that involves the parents developing a routine at bedtime that is characterized by quiet and enjoyable activities for the child. Faded Bedtime is often used with Positive Routines and involves taking the child out of bed for predetermined periods of time when the child does not fall asleep. Bedtime is also delayed so that sleep onset occurs quickly and so that the cues for sleep are paired with the enjoyable activities from the Positive Routines procedure. Once the behavioral chain of events is well established and the child falls asleep more quickly, bedtime is moved earlier by 15–30 min over successive nights until an age appropriate bedtime goal is achieved. In addition, when overnight wakings are the primary problem, scheduled awakenings can be used. This procedure involves the parent awakening and comforting their child approximately 15–30 min before a typical awakening. Before using this strategy, a baseline of the number and timing of the nighttime awakenings must be established. Preemptive awakenings are then scheduled and can involve rocking or nursing the child back to sleep. Over consecutive nights, scheduled awakenings are faded out, by gradually increasing the time span between awakenings. Scheduled awakenings have been shown to increase the duration of consolidated sleep (Rickert & Johnson, 1988).

Another approach to treatment of sleep disturbances is to prevent their occurrence. A number of behavioral interventions have been incorporated into new parent education programs. These programs typically focus on early establishment of positive sleep habits. Education in these programs targets bedtime routines, development of a consistent schedule, parental soothing techniques during sleep initiation, and parent response

Table 70.2 Stimulus control and sleep restriction: intervention and rationale.

Stimulus control therapy (Bootzin, 1979)

Rationale. Conditioning has occurred between temporal and environmental stimuli (the bed, bedroom, and bedtime) normally conducive to sleep and sleep incompatible behaviors (e.g. worry/frustration at not being able to sleep), such that the bed, bedroom, and bedtime are no longer discriminative stimuli for sleep. The intervention aims to reverse this maladaptive association by limiting the sleep incompatible behaviors engaged in within the bedroom environment thereby decreasing cues for sleep incompatible behaviors while increasing cues for sleep-compatible behaviors.

Intervention. The therapist provides a detailed rationale for and assists the patient to achieve the following

- (a) go to bed only when sleepy at night;
- (b) use the bed and bedroom only for sleep (i.e., no reading, TV watching, or worrying either during the day or at night);
- (c) get out of bed and go to another room whenever you are unable to fall asleep or return to sleep within 15–20 min and return to bed only when sleepy again;
- (d) repeat this last step as often as necessary throughout the night;
- (e) arise in the morning at the same time regardless of the amount of sleep obtained on the previous night (Bootzin *et al.*, 1991). Limited daytime napping (<1 hour) before 03:00 PM was made optional early in the treatment.

Sleep restriction therapy (Spielman *et al.*, 1987)

Rationale. Derived from the proposal that excessive time in bed perpetuates insomnia. The intervention involves curtailing time in bed to the actual time slept and gradually increasing it back to an optimal sleep time.

Intervention. Based on sleep diary data, each patient is prescribed a specific amount of time in bed (sleep window) not to be exceeded. The duration of this sleep window is reviewed weekly and increased or decreased contingent upon the sleep efficiency for the previous week. The goal is to maximize sleep efficiency [(total sleep time divided by time in bed) × 100] to more than 85%.

to nighttime awakenings. Additionally, almost all programs recommend that parents should put babies to bed “drowsy but awake” so that they can develop independent sleep initiation skills. Moreover, this can help babies return to sleep without parental intervention following naturally occurring nighttime arousals. Among the forms of behavioral health services for children, no other treatment has been more thoroughly researched or broadly applied as parent education training (Kazdin, 2005).

In a recent review of behavioral interventions, the average percentage of infants and young children who improved was 82% (range 10–100%) (Mindell *et al.*, 2006). Overall, the weight of the evidence from controlled group studies supports unmodified extinction and parent education/prevention. Graduated extinction, bedtime fading/positive routines, and scheduled awakenings are also well supported in the empirical literature. Standardized bedtime routines and positive reinforcement techniques have often been incorporated as part of a multicomponent treatment package; however, there is limited empirical support for their effectiveness as stand-alone interventions.

Problems going to sleep and staying asleep in older children and adolescents

Insomnia

Insomnia is a common complaint among older children and adolescents, particularly sleep-onset insomnia. Cognitive behavioral treatments for insomnia (CBT-I) include a range of powerful behavioral adjustments to sleep. The evidence that CBT-I produces reliable and durable changes in sleep in adults has been summarized in multiple meta-analyses and two practice parameters commissioned by the American Academy of Sleep Medicine (Morin *et al.*, 1999, 2006). Among youth, there is less evidence for the use of CBT-I. However, this is a growing area of research. For example, Bootzin and Stevens (2005) conducted an uncontrolled trial of CBT-I for adolescents with insomnia and substance use problems ($n = 55$). Self-reported drug problems declined for completers at follow-up evaluation while continuing to increase for noncompleters. In a separate report, improvements in sleep were associated with significant decreases in aggressive thoughts and actions (Haynes *et al.*, 2006). Another small ($n = 18$) uncontrolled pilot (Schlarb *et al.*, 2010) of a six-session insomnia behavioral therapy (BT-I) found improvement in numerous sleep parameters. While both of these trials have been limited by the lack of a randomized control condition, the generally positive results are encouraging. These data show the feasibility of improving sleep through a short-term psychological intervention in adolescents and provide promising preliminary results suggesting that improved sleep in youth can contribute to improvements in behavioral and emotional functioning. Moreover, Cain *et al.* (2011) attempted to address common problems of low motivation for treatment, poor treatment adherence, and attrition among adolescent patients by using the school classroom as an alternative arena for sleep intervention. Despite self-reported increases in motivation

to improve their sleep, sleep patterns, and daytime functioning were not significantly different between the intervention and control groups at post treatment. Although promising, these findings might be interpreted to suggest that even in the face of adequate motivation, adolescents require parental and/or clinician assistance in regulating and maintaining healthy sleep schedules.

There are a range of important components of a behavioral intervention for insomnia as depicted in Figure 70.1 and described in detail elsewhere (Harvey, 2009; Clarke & Harvey, 2012).

“Nights-owls” and delayed sleep phase syndrome (DSPS)

There is evidence that the onset of puberty triggers a change toward a distinct evening preference among approximately 40% of teens (Carskadon *et al.*, 1997; Roenneberg *et al.*, 2004), which is then exacerbated by various social (e.g., importance of peers, parents less involved in decisions regarding bed and wake times), psychological (e.g., increased pressure at school) and behavioral factors (e.g., use of social media in bed and during the night). Together these factors can contribute to a tendency toward eveningness or, in the extreme, delayed sleep phase syndrome (DSPS). Problems with delayed sleep in children and adolescents can be further compounded by large differences between weekday and weekend schedules, so-called “social jetlag.”

There is a small treatment literature on DSPS in teens, including the use of timed light with teens (Crowley *et al.*, 2007), as well as practice parameters (Sack *et al.*, 2007) that indicate evidence for timed light exposure (with a light box) and planned and regular sleep schedules (chronotherapy) in adults. Moreover, Gradisar *et al.* (2011) evaluated six sessions of CBT-I plus morning bright light therapy (BLT) to advance sleep onset (CBT-I plus BLT) versus wait-list for adolescents diagnosed with delayed sleep phase disorder (DSPD). CBT-I plus BLT was associated with reduced sleep latency, earlier sleep onset and rise times, total sleep time (school nights), wake after sleep onset, sleepiness, and fatigue. At 6-month follow-up, these improvements were sustained. Unfortunately, it can be difficult to motivate teens to use light boxes and to participate in delaying chronotherapy. Traditional chronotherapy involving progressively delaying bedtimes and waketimes until reaching the desired alignment tend to be highly disruptive to family and work schedules. Hence, we suggest adopting a planned sleep modification protocol derived from circadian principles involving moving bedtimes earlier by 20–30 min per week. The circadian system can adapt to more rapid changes but we find it is better to build a sense of mastery and control over sleep with smaller changes, scaffolded with interventions focused on wind-down and wake-ups. The targets depicted in Figure 70.1 are additional treatment offerings within this class of problems.

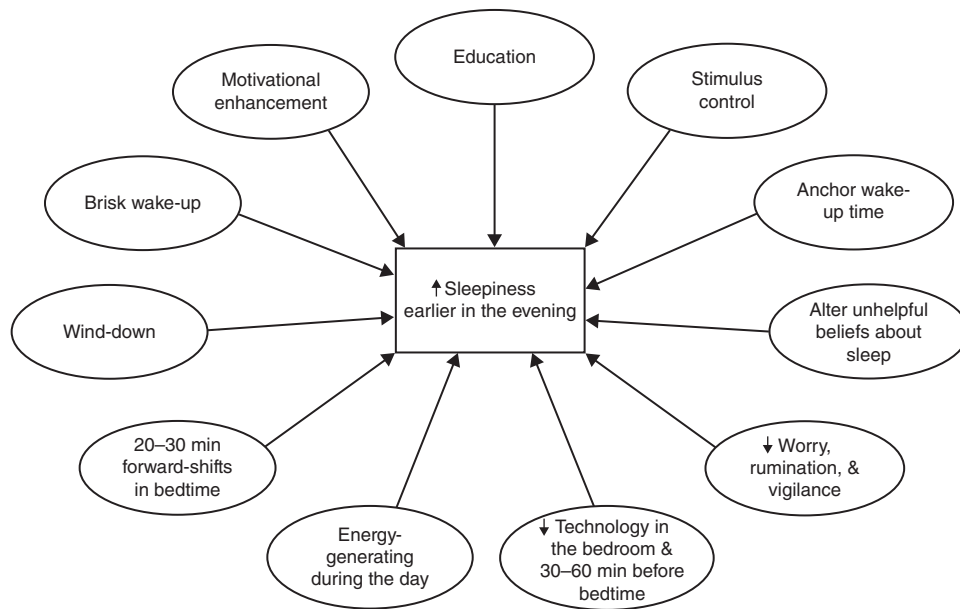

Figure 70.1 Targets for improving sleep in children and adolescents.

Daytime sleepiness/difficulty waking up for school

After the onset of puberty and throughout the adolescent period, the most prevalent sleep complaints tend to center on difficulty waking up for school in the morning and the associated difficulties with daytime sleepiness, tiredness, and irritability. It is important to emphasize that there is a broad continuum of severity. This ranges from normative/mild difficulties that appear to affect up to half of all high school students in the United States and result in at least some symptoms (National Sleep Foundation, 2006) to a much smaller subset of adolescents with severe difficulties with sleep and schedules that result in significant impairments (such as failures in school) and often meet full criteria for DSPS. At the current time, there is an absence of empirical data to help delineate precisely when to diagnose adolescents as having DSPS disorder from the much larger set of youth with mild-to-moderate problems with erratic and late sleep schedules. One pragmatic approach is that clinicians understand both the physiologic and social influences that contribute to these problems, and apply sound behavioral principles aimed at improving and increasing sleep in any adolescent who shows evidence of suboptimal sleep as a result of late night and erratic schedules, as already described. In the adolescents with true sleepiness (not simply complaints of fatigue), two main categories of problems should be considered: (i) Inadequate amounts of sleep and (ii) circadian and scheduling disorders. Circadian disorders (DSPS) were discussed earlier. In terms of inadequate amounts of sleep, the most common cause of mild-to-moderate sleepiness in adolescents is an inadequate number of hours in bed. A combination of social schedules leading to late nights with early-morning school requirements can significantly compress the number of

hours of sleep. Part-time jobs, sports activities, hobbies, and active social lives can exacerbate this problem. The catch-up sleep of naps, weekends, and holidays can also contribute to the problem by leading to erratic schedules and even later nights. In taking a sleep history, it is important to ask specific questions about bedtime schedules. Many families will say the adolescent “usually” goes to bed at a certain time, but when asked for an exact time covering the previous few nights, a much later hour is reported. When assessing the amount of sleep an adolescent is getting, it is important to obtain details of bedtime (such as when the child gets into bed as well as lights-out time), estimates of sleep latency, nighttime arousals, time of getting up in the morning, difficulty getting up, and the frequency, timing, and duration of daytime naps. It is also essential to get details of sleep/wake schedules on weekends, as well as during the school week. When this type of specific information is obtained either by interview or by having the family maintain a sleep diary, evidence of inadequate sleep is often evident. A prospective detailed sleep diary provides the most reliable information.

When inadequate sleep is identified, simply recommending that the adolescent go to bed earlier is not likely to be effective. Often, the primary role of the clinician is to help the entire family understand and acknowledge the consequences resulting from the inadequate sleep. Sleep deprivation frequently contributes to many factors that the family identifies as problems, including falling asleep in school, oversleeping in the morning, fatigue, and irritability. In cases in which the adolescent’s school or social functioning is significantly impaired by sleep problems, a strict behavioral contract that is agreed upon by the family can be essential. The contract should specify hours in bed (with only small deviations on the weekends) and should target the specific behaviors contributing to bad sleep habits, such as specific

late-night activities, erratic napping, or oversleeping for school (see Figure 70.1). The choice of rewards for successes and negative consequences for failures, as well as an accurate method of assessing compliance, are essential components of the contract. Many of the other behavioral components outlined earlier for DSPS can also be used to treat children and teens with excessive daytime sleepiness.

Parasomnias

Parasomnias occur commonly in children as sudden, partial awakenings from deep, non-REM sleep into a mixed state which has some aspects of being awake and some aspects of being in a deep sleep. There appear to be at least two routes to this mixed state: (i) difficulty leaving deep sleep (Stages 3 and 4) at the end of the first sleep cycle, or (ii) a sudden disturbance or disruption during the middle of deep sleep. The events include sleepwalking, night terrors, and confused partial arousals (some enuretic events can also occur as partial arousals). The intense events (with screaming, agitated flailing, and running) represent the extreme end of a spectrum of partial arousal behaviors that occur in mild forms (such as calm mumbling or a few awkward movements) in many children. The events can last from a few seconds to 20 min, with an average duration of about 3 minutes. The termination is usually as sudden as the initiation, with a rapid return to deep sleep. During the events, the children may seem confused, often not recognizing their parents, being inconsolable, and often appearing incoherent.

Overtiredness from any source (whether sleep deprivation, sleep disruption, or erratic schedule) can increase or precipitate parasomnias. Any time a child is adjusting to getting less sleep, or has disturbed nighttime sleep, the physiological compensation is to get deeper sleep (especially in the first 1 to 2 hours after sleep onset). This deep “recovery” sleep appears to be fertile ground for partial arousal events. When a parasomnia is suspected, the clinical interview should include obtaining a careful history of all sleep-related habits, as well as the characteristics, pattern, and frequency of the events. Occurrence in the first third of the night and an increased frequency corresponding to periods of being overly tired are strongly suggestive of typical parasomnia events.

Given the wide range of intensity of these nocturnal partial arousals, the key to therapy is matching the appropriate intervention to the degree of problem. That is, mild sleepwalking or an occasional night terror in a young child requires only some parental reassurance with general suggestions regarding improved sleep habits and the likelihood that the events will decrease over time. First, educate the family about the events (and what to do during the actual partial arousal event). For mild-to-moderate events, the parents should try to direct the child to go back to bed and back to sleep. Physically taking the child by the hand and leading him/her back to bed during a mild event can also be effective. Usually, however, the event needs to take its course and will end spontaneously. During more agitated arousals, interventions trying to direct the child

back to bed can result in increased arousal and can inadvertently prolong the event. In general, if mild directing of the child does not work, the parents should let the episode run its course. One very important caveat to this advice is with respect to the need to prevent self-injury. Eliminating factors such as sleeping on the top bunk bed, having a bedroom near the top of the stairs, or having windows or dangerous objects in the room are major considerations.

Second, encourage a regular sleep/wake schedule with good sleep habits. The parents should consider an earlier bedtime if there is any evidence that the child is getting inadequate sleep. Specific causes of delayed bedtime or difficulty falling asleep should also be directly addressed. It is important to try to improve the overall quantity and/or quality of sleep of the child when applicable.

Finally, for the more frequent, repetitive, intense, and agitated sleep terrors, these can be treated effectively through the use of scheduled awakenings (Durand, 2002). Similar to the scheduled awakenings described previously, the child is lightly awakened and allowed to fall back to sleep 15–30 min before the usual time of the episodes (Durand, 2008). After about a week of this intervention, the sleep terrors typically are reduced or eliminated.

One final important note, certain types of epilepsy, particularly nocturnal frontal lobe epilepsy often occurs during sleep. As a result, it can be extremely challenging for the clinician to distinguish from parasomnias. The interested reader is referred to a comprehensive overview of the issues and controversies (Bisulli *et al.*, 2011).

Sleep-disordered breathing

Sleep apnea and a related set of problems called sleep-disordered breathing (SDB) can contribute to fragmented sleep that can subsequently contribute to daytime difficulties with cognitive and affective functioning. Rosen *et al.* (2003) conducted a prospective, cross-sectional study of 850 children. The overall prevalence of sleep-disordered breathing was 2.2%. However, black children were four to six times more likely to exhibit SDB relative to white children and children who were preterm babies were three to five times more likely to have SDB relative to those who were not preterm. Difficulties with irritability, attentional difficulties, and emotional lability can be created and/or exacerbated by sleep-disordered breathing in children. Although the actual number of minutes of arousal during the night may be small, the repeated, chronic, but brief disruptions in sleep can lead to significant daytime symptoms in children. It is important to note that the child is usually unaware of waking up, and the parent often describes very restless sleep but usually does not describe the child's waking up completely. The most frequent symptoms reported by families include loud chronic snoring (or noisy breathing), restless sleep with unusual sleeping positions (attempts by the child to move and open the airway), a history of problems with tonsils, adenoids, and/or ear infections, and signs of inadequate nighttime sleep. In medical centers with pediatric sleep facilities, consultation with a child

sleep specialist can be extremely helpful in sorting out treatment decisions in these cases.

Restless leg syndrome (RLS) and periodic limb movement disorder (PLMD)

Restless leg syndrome (RLS) is a clinical diagnosis characterized by disagreeable leg sensations that usually occur before sleep onset. PLMD is characterized by periodic episodes of repetitive and highly stereotypic limb movements during sleep with symptoms of insomnia or excessive daytime sleepiness (Chesson *et al.*, 1999). PLMD and RLS are distinct entities but can coexist. Most patients with PLMD do not manifest RLS symptoms; however, approximately 80% of patients with RLS have PLMD (Montplaisir *et al.*, 1997).

PLMD has been described in children with somewhat different clinical presentation. Children with PLMD may present with nonspecific symptoms such as growing pains, restless sleep, and hyperactivity (Picchietti & Walters, 1999). These symptoms are most often unnoticed by their parents, although a family history of RLS and PLMD is common.

In terms of treatment, the guideline from the Standard of Practice Committee of the American Academy of Sleep Medicine states that no specific recommendation can be made regarding treatment of children with RLS or PLMD (Littner *et al.*, 2004). Other reviews highlight the role of iron deficiency in exacerbating symptoms and explore a potential role for iron supplementation (Picchietti & Picchietti, 2008). Clearly this is an important domain for future research.

Narcolepsy

Narcolepsy is a chronic neurological disorder characterized by excessive daytime sleepiness. The classic symptoms include: (i) sleep attacks, (ii) cataplexy (the sudden loss of muscle tone without change of consciousness), (iii) sleep paralysis (inability to move after waking up), and (iv) hypnagogic hallucinations (dream-like imagery before falling asleep). These symptoms do not all occur together or consistently in many cases of narcolepsy. Particularly in younger patients, signs of sleepiness may be the only initial symptom. Cataplexy is typically provoked by laughter, anger, or sudden emotional changes. It may be as subtle as a slight weakness in the legs, or as dramatic as a patient's falling to the floor limp and unable to move.

The diagnosis of narcolepsy requires evaluation in a sleep laboratory. Treatment of narcolepsy is generally focused on education and counseling of the patient and family, adherence to a regular schedule to obtain optimal sleep with good sleep habits (often including scheduled naps), tests for human leukocyte antigens (HLAs), and cerebrospinal fluid hypocretin (Hcrt) measurement (Nevsimalova, 2009) and use of short-acting stimulant medication for treatment of daytime sleepiness (with drug holidays to avoid build-up of tolerance). Moreover, there are problems and a need for research. Modafinil, a common treatment for narcolepsy, blocks dopamine transporters and increases dopamine in the brain (including the nucleus

accumbens). Accordingly, there is potential for abuse and dependence (Volkow *et al.*, 2009) and no knowledge about the impact on the developing brain.

Finally, we highlight possible associations between ADHD and narcolepsy. In a retrospective history of childhood ADHD symptoms among a large sample of adults with narcolepsy ($n=161$) and controls ($n=117$), childhood ADHD symptoms were 8–15 times greater than expected (Modestino & Winchester, 2013). Although limited by the retrospective and cross-sectional methodology, these findings highlight a possible domain for future research.

Hypersomnia

The differential diagnosis of narcolepsy includes consideration of idiopathic hypersomnia. Excessive daytime sleepiness is common among youth, especially youth with a mood disorder. In addition, during phases of depression patients commonly suffer from periods of hypersomnia (Kupfer *et al.*, 1972). Hypersomnia has adverse consequences for school attendance and performance, relationships, mood, and sense of self-worth. There is very little existing literature on the mechanisms that contribute to hypersomnia in mood disorder, nor the methods to treat it (Kaplan & Harvey, 2009). In our clinical experience, treating hypersomnia is likely to begin with goal setting, which involves reducing nightly sleep as well as setting goals for life. The latter is based on our clinical experience that “having nothing I am looking forward to get up for” can be a key contributor to hypersomnia. Often the combination of the mood disorder and the sleep disorder has led to school disengagement/drop-out and/or disrupted social networks. After setting the “sleep” and “life” goals for the treatment, the young person is asked to identify one small step toward these goals for the coming week. After a detailed discussion of how to achieve those goals, possible obstacles are identified. We engage in problem solving to limit the impact of these obstacles on reaching the goal, and a method is developed for monitoring the extent to which the goal is achieved (Kaplan & Harvey, 2009).

Medications

Several classes of medications are used for treating sleep problems, particularly insomnia; namely, benzodiazepine receptor agonists, sedating antidepressants, antihistamines, and melatonin agonists. Benzodiazepine receptor agonists (BRAs), which include traditional benzodiazepines (e.g., temazepam, flurazepam) and nonbenzodiazepine hypnotics (e.g., zolpidem, eszopiclone, and zaleplon) also acting on the GABA receptor complex, have been extensively evaluated in controlled clinical trials in adults (Walsh *et al.*, 2005). The main therapeutic effects involve improvement in sleep continuity and efficiency through a reduction of sleep onset latency and time awake after sleep onset; in addition, they increase total sleep time and reduce the number of awakenings and stage shifts through the night. Benzodiazepines tend to reduce slow-wave (Stages 3–4) sleep and REM sleep, but these changes are less pronounced

with zolpidem and eszopiclone (Langtry & Benfield, 1990; Hoehns & Perry, 1993; Wadworth & McTavish, 1993). All hypnotic medications carry some risks of daytime residual effects (e.g., cognitive and psychomotor impairments), as well as risks of tolerance and dependence. These risks vary with dosage, half-life, duration of use, and individual factors (e.g., age and gender). In general, short-acting drugs have fewer residual next-day effects than long-acting medications. When used on a regular and prolonged basis, there are also risks of tolerance and dependence, which vary across individuals. Rebound insomnia is a common problem associated with rapid discontinuation of benzodiazepine-hypnotics, particularly after prolonged usage. In general, the newer BRAs produce fewer withdrawal symptoms upon discontinuation. In addition, most studies have not included a follow-up to determine whether gains are sustained after treatment cessation. Thus, the durability of the improvement to sleep associated with pharmacological treatment is not well documented.

It is emphasized that, to the best of our knowledge, all of the data just reviewed are derived from adults. Mindell and Owens (2009) highlight that few studies have been conducted on hypnotic medications in children and they warn about the possibilities that prescribing a medication may even send an unhelpful message to parents; namely, instead of emphasizing basic good sleep habits and inspiring a family toward behavior change, a medication might just maintain or cover up the problems that are truly maintaining the sleep problem. A survey completed by 1273 members of the American Academy of Child and Adolescent Psychiatry indicated that about two-thirds of child psychiatrists reported recommending nonprescription antihistamines, while more than one-third had recommended melatonin (Owens *et al.*, 2010b). Antihistamines have a relatively long half-life. As a result, drowsiness and clumsiness are common side effects and tolerance can develop within 3–4 days (Schweitzer, 2011). While there have been trials of melatonin for teens (Jan *et al.*, 2000; Szeinberg *et al.*, 2000), including an open trial among 15 children with Asperger's Disorder (Cortesi *et al.*, 2012), there are safety concerns about the impact on the reproductive endocrine system (Arendt, 1997; Malpoux *et al.*, 1999; Wyatt, 2007). Note also that a trial of zolpidem failed to improve polysomnographically measured sleep in 6–17-year-olds who met diagnostic criteria for insomnia associated with ADHD (Blumer *et al.*, 2009). Moreover, there are serious questions about whether the sleep obtained confers the full benefit of “natural” sleep or sleep in the absence of medications (Seibt *et al.*, 2008). For example, Seibt and colleagues (2008) investigated the impact of Zolpidem (Ambien) on the development of the visual system in kittens 28–41 days old. As expected, Zolpidem increased NREM sleep by 27% and increased total sleep over the 8-hour period. However, rather alarmingly, Zolpidem reduced cortical plasticity by 50%. The authors concluded that hypnotics that produce more “physiological” sleep based

on EEG may actually impair critical sleep-dependent brain processes during development. This finding should stimulate new research into the safety of certain pharmacologic agents, particularly regarding impacts on the developing bodies and brains of children and adolescents. In sum, starting treatment with a quality behavioral intervention is recommended so as to avoid concerns about safety and efficacy. Another important consideration, and domain for future research, is concerns about possible sleep disturbances attributed to medications used to treat common childhood disorders such as ADHD.

Technology use

This is a topic that deserves a special section. As discussed in Section “Basic overview of human sleep architecture across development,” the process by which the human circadian clock is set to a 24-hour period and kept in appropriate phase with seasonally shifting day length is called entrainment, which occurs via *zeitgebers*. The primary *zeitgeber* is the daily alteration of *light* and *dark*. The light-entrainable SCN synchronizes networks of subordinate circadian oscillators controlling fluctuations in other brain regions and, in particular, in neural circuitry supporting reward seeking (centered on ventral striatum) (Venkatraman *et al.*, 2007) and emotion processing (centered on amygdala and orbitomedial PFC) (Yoo *et al.*, 2007), two circuits highly relevant to risk taking among teens and that continue developing well into the teenage years (Giedd *et al.*, 1999; Blake-more *et al.*, 2010). Hence, an intervention to improve sleep incorporates timed light exposure and inevitably needs to address exposure to sources of light in the hour before bed, via the use of cell phones, laptops, social networking etc. The National Sleep Foundation (NSF) Poll focused on technology in 2012. In the 13–19-year-old age group, well over 90% were using some kind of technology the hour before bed: 54% watched television, 72% used their cell phones, 60% their laptops, 64% their music maker, and 23% play video games every night or almost every night within the hour before going to sleep. These behaviors have multiple potential adverse impacts on sleep. The artificial light exposure suppresses release of the sleepiness-promoting hormone melatonin, enhances alertness and shifts circadian rhythms to a later hour. Technology is also highly arousing and engaging and facilitates the much-loved contact with peers. These influences are so potent that it is very difficult for many teens to switch media devices off at night, delaying bedtimes still further (National Sleep Foundation, 2011). Moreover, cell phones are, too often, a source of sleep disturbance during the night. About 1 in 10 of 13–19-year-olds in the NSF poll reported being awakened after they go to bed every night or almost every night by a phone call, text message or email. Clearly, these are modifiable sources of sleep disturbance. Accordingly, technology use is represented as a target in Figure 70.1.

Conclusions and future directions

In this chapter, we have reviewed several important principles relevant to the assessment, diagnosis, and treatment of sleep problems in children and adolescents. We have underscored the evidence for interactions between sleep and the regulation of behavior, emotion, and learning. We have particularly emphasized behavioral principles and behavioral approaches to these problems because we believe that there is great pragmatic and clinical value in understanding and implementing these in many domains of clinical practice.

Unfortunately, knowledge of sleep problems and treatments is not widely disseminated to the public and this may be contributing to the epidemic of sleep deprivation among children and adolescents. As highlighted earlier, the most effective method for “treating” sleep problems is to prevent them before they start. Parent education about normative sleep across the first year of life has been critical in reducing many common sleep problems among infants and young children. However, to our knowledge, this approach has not been utilized among parents of school-age children and teenagers. It is possible that the sleep problems in later childhood and adolescence could be prevented by educating parents about developmental sleep needs, healthy sleep habits, how to set clear limits around technology use at bedtime and how to *model* healthy sleep to their children. Additionally, teachers, coaches, and health care providers could enhance prevention efforts through receiving education on the common “red flags” of poor sleep among children and teens (e.g., falling asleep in class and snoring). Early work in this area has piloted a screening tool for assessing sleep problems in pediatric primary care clinics (Owens & Dalzell, 2005). A potential next step may be to introduce prevention programs in schools and primary care clinics aimed at encouraging healthy sleep and providing extra support for children and teens that show early signs of sleep disruption (e.g., excessive sleepiness in class). This type of work has the potential to provide the most economical and time efficient approach to the treatment of pediatric sleep problems. However, equally important to the prevention of pediatric sleep problems is the removal of societal and environmental barriers to healthy sleep. For example, one barrier to healthy sleep among adolescents may be early school start time. Recent evidence indicates that a 30-min delay in school start time (from 8:00 AM to 8:30 AM) is associated with significant improvements in measures of adolescent alertness, mood, and health (Owens *et al.*, 2010a).

While there is significant evidence that sleep problems predict the development of future physical illness (e.g., Cappuccio *et al.*, 2008) and psychiatric problems (e.g., Choquet *et al.*, 1993) and that behavioral interventions for sleep disturbances in childhood and adolescence are effective, there remain several areas requiring future research. First, the risk factors associated with the development of sleep problems need to be better

identified and defined. Critically, this has the potential to lead to even more powerful intervention and prevention efforts. Furthermore, the impact of potential moderating variables (e.g., child temperament, household socioeconomic status, etc.) on treatment outcomes needs to be examined with a focus on the potential long-term impact that behavioral interventions may have on the persistence of sleep problems in adulthood. Also important will be the evaluation of behavioral treatments in children with special needs including children with autism spectrum disorders, mental retardation, and neurodevelopmental disabilities and children with chronic medical and psychiatric conditions.

Although there is much research and work yet to be carried out, we have highlighted in this chapter the encouraging evidence that there are few risks—and potentially many benefits—from increasing and enhancing sleep in children and adolescents through cognitive and behavioral interventions. Further dissemination of this evidence may offer considerable assistance in providing all children and adolescents the best opportunities for reaching their physical, educational, and psychological potential via healthy sleep habits. As medication treatments are explored, it is essential that the impact of the developing body and brain be established (Seibt *et al.*, 2008).

Finally, there is growing promising research on sleep deprivation (Gorgulu & Caliyurt, 2009), light therapy (Benedetti *et al.*, 2007), and dark therapy (Barbini *et al.*, 2005) for patients with mood disorders. While the preliminary studies in adults are very interesting and promising, the application of these novel treatment approaches in children remains to be explored.

CHAPTER 71

Feeding and eating disorders

Rachel Bryant-Waugh and Beth Watkins

Department of Child and Adolescent Mental Health, Great Ormond Street Hospital for Children NHS Foundation Trust, London, UK

Introduction

The aim of this chapter is to provide the reader with a comprehensive update on feeding and eating disorders encountered in child and adolescent mental health care settings. Our intention is to provide a scholarly update and clinically useful chapter. Detail is provided on diagnosis and clinical presentation, followed by information on epidemiology, risk factors, and etiology. Subsequent sections cover assessment, treatment, and outcome.

This chapter focuses on feeding and eating disturbances that are considered “psychiatric” or “mental” disorders, rather than those that represent normal developmental variations or behavior experienced as problematic by the parent or caregiver. The situation is complicated in childhood and adolescence as feeding and eating takes place in an interpersonal context due to normal age-appropriate dependencies, which has led some to argue that childhood feeding difficulties should be reconceptualized as interactional disorders (Davies *et al.*, 2006).

Feeding and eating disorders can be serious and damaging conditions, associated with relatively high levels of morbidity and mortality. In this chapter, we cover anorexia nervosa (AN), bulimia nervosa (BN), binge eating disorder (BED), avoidant/restrictive food intake disorder (ARFID), pica, and rumination disorder. The chapter does not include obesity as there is little evidence to support its conceptualization as a mental disorder. However, it is recommended that body mass index (BMI) should routinely be monitored in those with a psychiatric disorder (Marcus & Wildes, 2009).

To put the rest of this chapter in context, we refer briefly to the development of successful early feeding and later independent, normal eating behavior. The establishment of problem-free feeding requires the physical ability and a desire to feed, as well as the presence of an appropriate caregiver with access to suitable food. Individual, interpersonal, and environmental factors can adversely affect feeding, with successful early feeding depending

on a range of factors coming together simultaneously. Infant and caregiver need to adapt their behaviors and responses as developmental tasks are negotiated in the context of food intake and a more independent pattern of childhood eating becomes established. As children move into adolescence, the arena of food choices, eating behavior, and mealtime interaction continues to be an important context for testing out developing individuation, self-expression, and autonomy.

Diagnosis and presentation

Children and adolescents with feeding or eating problems may come to clinical attention in a range of health care settings, including primary care and pediatric clinics as well as mental health settings. Combined with lack of consistency in use of terminology to describe different presentations and poor fit with existing diagnostic categories, we believe this has contributed to an unhelpful fragmentation of knowledge and expertise in this field, with associated difficulties in advancing the progress of research. It is important to make distinctions between a feeding or eating disturbance as a symptom of a medical condition; difficult feeding or eating as problem behavior; and a feeding or eating disturbance as a mental disorder. In practical terms, in order to determine whether a child is presenting with a feeding or eating problem that may be a clinically significant mental disorder, it can be useful to consider three main questions:

1 Is the problem consistent with normal variation for the appropriate developmental stage of the child? For example: acceptance of only a limited range of foods is normal around 2–4 years of age, but less so in older children; short periods of cutting down on certain foods with the aim of influencing weight or shape is common in adolescents and mostly benign, but when persistent, extreme and accompanied by significant weight loss may be a cause for concern.

2 Is there risk in relation to consequences if left unaddressed?

To establish whether there is impairment to development and functioning, both psychological and physical.

3 Can the eating disturbance be primarily accounted for by a medical condition? If the answer is yes, it is unlikely to be a mental disorder, although in some instances an episode of illness or a medical condition may be a relevant part of the presentation.

This chapter focuses on the feeding and eating disorders recognized as mental or behavioral disorders by the two main classification systems relevant to mental health: the American Psychiatric Association's Diagnostic and Statistical Manual (DSM-5) (American Psychiatric Association, 2013) and the World Health Organization's International Classification of Diseases (ICD-10) (World Health Organization, 1992). Two further classification systems warrant mention: DC:0-3R, relevant to infants (Zero to Three, 2005; see further Chapter 7) and Rome III, a system for classification of functional gastrointestinal disorders (Drossman *et al.*, 2006; see further Chapter 72). Each diagnosis is described briefly in the following sections, with common comorbidities and main differential diagnoses listed in Table 71.1 at the end of this section.

Pica

Pica is characterized by eating nonnutritive substances, which may be nonfood items or raw food ingredients eaten in large amounts. A diagnosis of pica is given when such behavior is persistent or sufficiently severe to warrant clinical intervention. Pica is not usually diagnosed where the ingestion of nonfood items is part of a culturally sanctioned practice, such as soil eating in many African communities (Geissler *et al.*, 1997), or when chronological or developmental age is below 2 years, as mouthing of objects with some ingestion is common. It may

occur in individuals with autism or those with learning disability (mental retardation) but can also occur in the context of normal development. Pica can lead to severe medical sequelae, to include poisoning and obstructions or perforations in the gastrointestinal tract. In some instances, it is associated with appetite loss, reduced intake, and weight loss and in extreme cases can be fatal.

Pica is a diagnosis applicable to children and adults in DSM-5 although in ICD-10 is classified as a disorder of infancy and childhood, but recognized as occurring in older individuals. Pica does not appear as a diagnosis in either the Rome III or 0-3R systems.

Rumination disorder

Rumination disorder is characterized by the repeated regurgitation of food that has been swallowed. The regurgitate is then rechewed (rumination) and reswallowed or spat out. The bringing back up of food occurs without undue effort and is not associated with nausea. Regurgitation should be differentiated from vomiting and gastroesophageal reflux. This behavior should be frequent, sustained over a period of time and not primarily accounted for by an underlying medical condition to warrant diagnosis. Repeated regurgitation can be associated with significant medical problems, to include malnutrition, low weight, dental problems, bad breath, and esophagitis. In extreme cases, rumination disorder can have a fatal outcome.

Rumination disorder occurs in children and adults, in those with intellectual disability as well normally developing individuals. It may have a soothing or calming function, playing a role in anxiety management or emotion regulation. It is often a secretive disorder and can be associated with significant impairment to social development and functioning. It can be associated with reduced intake and weight loss. Many clinicians fail to ask

Table 71.1 Differential and common comorbid diagnoses.

Feeding and eating disorder	Differential diagnosis	Common comorbid diagnoses
Feeding disorder	Reactive attachment disorder; neglect; medical conditions (to include oral dyspraxia)	Anxiety disorders; autism spectrum disorder; intellectual disability
Pica	Anorexia nervosa; avoidant/restrictive food intake disorder; factitious disorder; nonsuicidal self-harm	Avoidant/restrictive food intake disorder; obsessive-compulsive disorder; schizophrenia; autism spectrum disorder; intellectual disability
Rumination Disorder	Anorexia nervosa; bulimia nervosa; Gastrointestinal conditions	Generalized anxiety disorder; autism spectrum disorder; intellectual disability
Avoidant/Restrictive Food Intake Disorder	Anorexia nervosa; reactive attachment disorder; factitious or induced illness; specific phobia; social anxiety disorder; depressive disorder; medical conditions	Anxiety disorders; attention deficit hyperactivity disorder; autism spectrum disorder; intellectual disability
Anorexia Nervosa	Avoidant/restrictive food intake disorder; bulimia nervosa; body dysmorphic disorder; specific phobia; social anxiety disorder; depressive disorder; medical conditions	Depressive and anxiety disorders (including obsessive compulsive disorder)
Bulimia Nervosa	Anorexia nervosa; binge eating disorder; mood disorder; borderline personality disorder; Klein-Levine syndrome	Mood disorders; anxiety disorders; substance misuse; borderline personality disorder
Binge Eating Disorder	Bulimia nervosa; Prader-Willi syndrome; Klein-Levine syndrome	Mood disorders; anxiety disorders; substance misuse

questions related to the possible presence of rumination disorder, which can hinder identification and diagnosis (Hartmann *et al.*, 2012).

Rumination disorder is a diagnosis in DSM-5, with criteria applicable to infants, children, and adults. In ICD-10, rumination is included as a variant of feeding disorder of infancy and childhood, but not recognized as a specific disorder in older individuals. However, proposals for ICD-11 include establishing a new diagnostic category of rumination disorder with criteria applicable to both children and adults (Uher & Rutter, 2012). Rome III (Drossman *et al.*, 2006) has separate criteria for infant rumination syndrome, adolescent rumination syndrome, and rumination syndrome in adults. There is considerable overlap between the definitions of these presentations as functional gastrointestinal disorders and psychiatric disorders. Rumination disorder does not appear as a category in DC:0-3R (Zero to Three, 2005).

Avoidant/restrictive food intake disorder

ARFID is characterized by limited food intake, which can be in relation to the range of foods eaten, the overall amount of food eaten, or both, with a persistent failure to meet the individual's nutritional or energy needs. The disturbance in feeding or eating may be associated with a lack of interest in food, avoidance based on the sensory characteristics of food (e.g., texture and appearance), or a fear of the consequences of eating (e.g., choking and vomiting), and sometimes a combination of one or more of these. Patients presenting with ARFID might be underweight, normal, or less commonly, overweight. There may be accompanying growth faltering in young patients or significant nutritional compromise which in extreme cases can increase mortality risk. The criteria for ARFID allow for the fact that persistent food refusal may be managed clinically by the use of oral supplements or enteral feeds. The criteria also include impairment to psychosocial functioning as a possible main feature associated with the avoidance or restriction of food intake. Concern about weight and shape or avoidance of weight gain should be ruled out as this would suggest that AN might be a more appropriate diagnosis.

ARFID is a new diagnosis in DSM-5 (American Psychiatric Association, 2013) with criteria applicable to infants, children, and adults and planned to be included in ICD-11 (Uher & Rutter, 2012). It effectively replaces and extends feeding disorder of infancy or early childhood (DSM-IV; American Psychiatric Association, 1994), which has widely been regarded as too broad and nonspecific to be of much clinical relevance (Bryant-Waugh & Kreipe, 2012). The DC:0-3R classification system recognizes six separate categories of feeding behavior disorder but is limited to very young children (Zero to Three, 2005). Three of the DC:0-3R subcategories map on to well-described presentations in older children, such as food avoidance emotional disorder, selective eating, food phobias, and functional dysphagia (Nicholls & Bryant-Waugh, 2009). This contributed to the establishment of ARFID as a new diagnostic category

to capture presentations that are clearly separate from the weight/shape-related disorders of AN and BN, despite sharing restriction of food intake as a central feature, allowing for developmental differences in expression (Bryant-Waugh *et al.*, 2010). As it is a new diagnosis, epidemiological data are limited, but clinical experience suggests that ARFID has a more equal gender ratio than AN or BN.

Anorexia nervosa

AN is characterized by restriction of food intake leading to failure to meet energy requirements, weight loss, or maintenance at suboptimal level. Self-worth tends to be associated with weight and/or shape preoccupation. Despite being low weight, there is typically a failure to recognize this, accompanied by persistent efforts to avoid weight gain. Patients may or may not verbalize a fear of weight gain or becoming fat. Two subtypes are generally recognized, the restricting subtype and the binge-purge subtype (DSM-5; American Psychiatric Association, 2013). AN presents clinically in both boys and girls from around the age of 7–8 years, although more commonly in females (Nicholls & Bryant-Waugh, 2009). Very young patients tend to present with the restricting subtype of AN, with vomiting and then laxative misuse becoming more common features as age at presentation increases. Persistent under nutrition can adversely affect physical development and functioning, have irreversible effects such as permanent short stature and permanent deficits in bone mineral density (Katzman, 2005), and can have a fatal outcome. The mortality risk for AN is among the highest of all mental disorders.

AN is a diagnostic category in both DSM-5 and ICD-10. It does not appear in DC:0-3R or Rome III. Revisions to criteria in DSM-5 include rewording of the weight criterion to specify that weight should be less than is minimally normal, or for children and adolescents less than might be expected taking the individual's age, sex, stage of development, and physical health into account (Freidl *et al.*, 2012). Previously, many clinicians erroneously adhered to "85% of expected weight" (DSM-IV) or BMI of 17.5 or below as a diagnostic cut-off. The judgment of "minimally normal" and whether this is applicable to any one patient now lies with the clinician rather than being determined by population norms, although guidance suggests that the use of BMI percentiles can be useful. This is particularly important for younger patients as it has been reported that adolescents meeting criteria for AN but at 85–90% of their ideal body weight according to population norms often require hospital admission and can present with equally severe medical complications as those below 85% of ideal body weight (Peebles *et al.*, 2010). In DSM-5, severity of AN is rated on the basis of BMI percentile adjusted up or down depending on clinical symptoms, functional disability, and the need for supervision (DSM-5; American Psychiatric Association, 2013).

Wording changes have also been made to the cognitive criteria for clarification and to ensure better applicability to younger

patients. In DSM-IV, there was a requirement for the individual to express fear of weight gain or becoming fat; however, younger patients may not verbally endorse fear of fatness despite determined food refusal (Bravender *et al.*, 2010). Behavioral indicators or parent report are now accepted as valid sources of information so that the clinician can now draw on observation and reports from other informants. This is also relevant to cultural variations as individuals from some non-Western cultures appear identical to patients with AN, but may give other explanations for restricting their intake, such as fullness or abdominal discomfort (also known as non fat phobic AN, see further Becker *et al.* (2009)). The term “denial” in relation to acknowledging the seriousness of low weight has been removed and replaced with wording that implies that there may be an inability to appreciate the risks, consistent with the view that younger patients may have a reduced capacity for general risk appraisal (Bravender *et al.*, 2010). Finally, the amenorrhea criterion has been dropped, as it excluded several groups and there was insufficient evidence of clinical difference between patients with AN who menstruated versus those with amenorrhea (Attia & Roberto, 2009).

Bulimia nervosa

BN is characterized by binge eating episodes, defined as recurrent episodes of eating large amounts accompanied by a sense of loss of control. Binge eating is followed by behaviors intended to compensate for the amounts consumed to prevent weight gain, known as inappropriate compensatory behaviors. These include self-induced vomiting, laxative or other substance/medication misuse, excessive exercising, and fasting. As in AN, the individual's sense of self-worth is strongly influenced by self-perception of weight or shape. In most instances, individuals with BN tend to be of average or above average weight. Binge eating and purging behaviors tend to be secretive and accompanied by distress and feelings of shame and disgust. There may be a greater tendency to seek help than seen in AN. BN typically first presents in adolescence or adulthood, more frequently in female than male patients. Younger patients may be less likely to engage in laxative misuse, with self-induced vomiting being the most common purging behavior in younger adolescents. In some young people, BN may be associated with other “loss of control” behaviors such as self-harm, sexual promiscuity, and drug and alcohol misuse. Purging behaviors can have serious medical consequences such as electrolyte imbalance, cardiac arrhythmias, and dental decay. In extreme cases, repeated purging can have fatal consequences, for example, through cardiac complications or esophageal rupture.

BN is a diagnostic category in both DSM-5 and ICD-10. It does not appear in DC:0-3R or Rome III. Changes in DSM-5 include a reduction in the frequency criteria for binge eating episodes and compensatory behaviors to once a week over a 3-month period (Wilson & Sysko, 2009). A further change has been to abandon the requirement to specify subtypes, previously purging or nonpurging BN given insufficient supporting evidence for this

subdivision (van Hoeken *et al.*, 2009). Finally, severity ratings in DSM-5 allow the clinician to specify the severity of BN on the basis of the weekly frequency of inappropriate compensatory behaviors (Wolfe *et al.*, 2012).

Binge eating disorder

BED is characterized by recurrent episodes of eating large amounts accompanied by a sense of loss of control, similar to BN, but without the inappropriate compensatory behaviors. The binge eating is associated with marked distress, and a number of specific features, such as continuing to eat when full or eating when not hungry, eating rapidly, avoiding eating with others and feeling disgusted or guilty. Individuals with BED tend to be overweight or obese, and this condition is associated with increased health risks.

BED does not occur as a diagnostic category in either DSM-IV or ICD-10. In DSM-IV, it was included in the “residual” diagnostic category eating disorder not otherwise specified (EDNOS). It has now been included in DSM-5 on the basis of a review of its validity and clinical utility (Wonderlich *et al.*, 2009) and is a proposed new category in ICD-11 (Uher & Rutter, 2012). Previous DSM-IV research criteria for BED remain largely unchanged with the exception of changing the frequency criterion for binge eating episodes to once a week for 3 months and reducing the required duration of symptoms from 6 months to 3 months, both in line with BN. Severity ratings have been added, which in relation to BED allow the clinician to specify the severity of the disorder on the basis of the frequency of binge eating episodes per week (De Young *et al.*, 2012).

“Other” feeding and eating disorders and disturbances

Besides atypical and subthreshold presentations of the aforementioned disorders, there are two others that have been reasonably well characterized and investigated: purging disorder and night eating syndrome. As a result of limited clinical validity data, they do not appear as formal diagnostic categories in DSM-5, nor at this stage are they proposed to be included in ICD-11; however, they warrant brief mention here as disorders included in the residual feeding and eating disorder category. Studies on purging disorder, where normal weight individuals regularly engage in the use of inappropriate compensatory behaviors after eating normal or small amounts of food, have reported average age of onset around 20 years, although sporadic cases have been reported in older adolescents (Keel & Striegel-Moore, 2009). Night eating syndrome is less consistently defined, but most descriptions include three main features; consumption of a significant amount of food in the evening or night; disturbed sleep, often with consumption of food on waking up in the night; and lack of appetite in the morning (Striegel-Moore *et al.*, 2009). As with purging disorder, the majority of studies have been conducted with adults, suggesting that this presentation might be only rarely encountered in child and adolescent mental health care settings.

Epidemiology

Problems in epidemiological research and implications

Gathering reliable and valid epidemiological data for child and adolescent feeding and eating disorders has been challenging. Studies have used different methods of case detection making results difficult to compare. Community studies tend to report significantly higher incidence rates than studies using medical records, suggesting that there may be underreporting of the occurrence of these disorders as not all sufferers will present to health services (Smink *et al.*, 2012). Furthermore, some studies are based on psychiatric case registers while others involve general practitioner records. If a study focuses on only one type of data source, it is unlikely that all cases of interest will be detected.

Studies use different criteria and diagnostic systems, and as both DSM and ICD have been revised over time, more recent studies are not comparable with older studies. This point is particularly pertinent with the advent of DSM-5, which contains significant changes to diagnostic criteria. Additionally, diagnoses may be given by a variety of professionals working in diverse settings, and therefore it is difficult to ascertain whether a diagnostic system has been used reliably across professional disciplines and settings. More importantly, children and adolescents have been less likely to “fit” into formal eating disorder diagnostic categories (Nicholls *et al.*, 2000), suggesting that the epidemiological data to date may have underreported cases of significant feeding and eating disturbances in young people.

Further problems contributing to difficulties in interpreting and comparing the results of epidemiological studies include a focus on a specific geographical area, which may not be comparable to other areas across a number of variables, and most importantly, limited data from community studies that focus on incidence rates across a range of feeding and eating disorders in children and adolescents.

Trends over time

Meta-analyses have identified a small global increase in eating disorders throughout the 20th century (Keel & Klump, 2003), and a stable European incidence since the 1970s (Hoek & van Hoeken, 2003). Over time, improved case detection, greater public awareness leading to earlier case detection, and increased availability of treatment services may account for changes in incidence, rather than changes in rates being a true representation of any increase or decrease in occurrence of eating disorders (Hoek & van Hoeken, 2003; van Son *et al.*, 2006). Nevertheless, the incidence rate of eating disorders among 15–19-year-olds has increased (Smink *et al.*, 2012) and those with AN are presenting at an earlier age (van Son *et al.*, 2006).

Current knowledge of incidence and prevalence

In children aged 9 months to 7 years, more than 50% of parents report one problem feeding behavior and more than 20% report multiple problem feeding behaviors (Crist & Napier-Phillips, 2001). Parental report of feeding problems in children with

developmental disabilities and chronic medical conditions is estimated at 40–70% (Byers *et al.*, 2003) and this rises to up to 89% in children with ASD (Ledford *et al.*, 2008) and neurological impairment (Sullivan *et al.*, 2000). There are limited epidemiological data for pica in children and adolescents. Pica is reported to be relatively rare in healthy children over the age of 2 years in the United States (Marchi & Cohen, 1990), but pica eating may be more prevalent in specific populations, such as those with sickle cell anemia (Ivascu *et al.*, 2001). High prevalence rates of pica eating (up to 77%) have also been reported in school-age populations in Africa (Geissler *et al.*, 1998). The incidence and prevalence of rumination disorder in children and adolescents is unknown, partly due to variability in diagnostic terminology and partly due to regurgitation and rumination often occurring in secret (Hartmann *et al.*, 2012).

The incidence of AN and BN is highest in adolescent girls (Lewinsohn *et al.*, 2000), with reported rates in 15–19-year-olds ranging from 109 to 270 per 100,000 person years for cases reported in primary care and from a community sample, respectively (van Son *et al.*, 2006; Keski-Rahkonen *et al.*, 2007). Incidence rates of 34.6 per 100,000 person years for AN and 35.8 per 100,000 person years for BN in a UK study were found in females aged 10–19 years (Currin *et al.*, 2005). Turnbull *et al.* (1996) reported an incidence rate of AN of 17.5 per 100,000 person years in 10–19-year-olds, and 0.3 per 100,000 person years in 0–9-year-olds.

Three recent national pediatric surveillance studies found an incidence rate of restrictive eating disorders with onset aged 13 years or younger from 1.4 to 3.0 per 100,000 (Madden *et al.*, 2009; Nicholls *et al.*, 2011; Pinhas *et al.*, 2011). One study identified a clear relationship between incidence and increasing age, with no cases found in individuals aged 5 years, and 9.51 per 100,000 person years in individuals aged 12–13 years (Nicholls *et al.*, 2011).

Prevalence rates of eating disorders in children and adolescents vary depending on the country and age range studied. Stice *et al.* (2009) reported a lifetime prevalence by age 20 years of 0.6% for AN, 2.0% for broad AN (i.e., below the diagnostic threshold), 1.6% for BN, and 2.4% for EDNOS, while Machado *et al.* (2007) found a point prevalence of 0.39% for AN and 0.64% for broad AN among adolescent girls. Community studies that used dimensional measures in adolescents have found high prevalence rates of 14–22% of eating disordered behaviors (Jones *et al.*, 2001; Hölling & Schlack, 2007), but these rates drop significantly when strict DSM-IV diagnostic criteria were applied. A national comorbidity study in the United States found that the lifetime prevalence of eating disorders (defined broadly as AN, BN, and/or BED) in adolescents aged 13–18 years was 2.7% (Merikangas *et al.*, 2010) with rates of 0.3% for AN, 0.9% for BN, and 1.6% for BED (Swanson *et al.*, 2011).

Mortality

Meta-analysis of mortality studies, including studies of outcome in adolescents with eating disorders, found standardized

mortality ratios (ratio of observed deaths in the study population to expected deaths in the general population) of 5.86 for AN, 1.93 for BN, and 1.92 for EDNOS (Arcelus *et al.*, 2011). Data indicate that individuals with AN may be five to eight times more likely to die in the first 10 years following the diagnosis than individuals in the general population (Arcelus *et al.*, 2011; Franko *et al.*, 2013). This is substantially higher than is observed in individuals with major depression or alcohol abuse (Markkula, 2012).

Economic burden

A recent report investigated the economic impact of eating disorders in England, taking a specific focus on young people. Taking into account health care costs, premature mortality, education, employment, and gross domestic product (GDP), the economic cost of eating disorders is over £1.25 billion (just under 2 billion US dollars) per year. While there are substantial costs for health care (estimated at £80 million or around 125 million US dollars), the report concludes that the human costs and cost of lost output are likely to be significantly greater (Pro Bono Economics, 2012). Young people aged 10–19 make up approximately 45% of hospital admissions, suggesting that 45% of National Health Service costs in England for treating eating disorders were attributable to those aged under 20, and in the period from July 2009–June 2010, across all age ranges, hospital admissions for eating disorders in England increased by 11% in comparison to the previous 12 months (Hospital Episode Statistics, 2010). In addition, there is significant private provision of services for the treatment of eating disorders, with approximately 27% of all CAMHS (child and adolescent mental health service) beds managed by the private sector. This figure increases to 82% for specialist eating disorder units (O’Herlihy *et al.*, 2003).

Risk factors and etiology

Feeding and eating disorders are varied, complex multifactorial disorders. There is little in the literature about risk factors for feeding disorders, pica, and rumination disorder. Indeed, for pica there are only hypothetical attempts to explain the condition (Rose *et al.*, 2000), which include nutritional deficiency and cultural factors. Pica is observed more commonly in areas of lower socioeconomic status, and traumatic events such as maternal deprivation, neglect, abuse, disorganized family structure, and poor parent–child interaction have been found to differentiate children with and without pica (Singhi *et al.*, 1981). There is no study that reports risk factors for rumination disorder or ARFID. This section, therefore, mostly focuses on the eating disorders AN, BN, and EDNOS.

Biological factors

Genetic factors

There have been significant advances in the study of genetic influences on eating disorders in the past decade. Previous research has shown that eating disorders aggregate in families. Twin studies have shown heritability for AN of between 58%

and 75% (Thornton *et al.*, 2011), for a broad anorexia phenotype of 48–74% and for BN of 54–83% (Bulik *et al.*, 2000) while heritability for BED has been estimated at 57% (Javaras *et al.*, 2008).

Eating disorder symptoms also appear to be heritable (Rutherford *et al.*, 1993; Sullivan *et al.*, 1998; Wade *et al.*, 1999; Klump *et al.*, 2000). Recent cross-sectional and longitudinal studies have identified developmental shifts in the etiological influences across adolescence. Pre- and early adolescent twins show lower heritability of eating disorder symptoms when compared to twins in mid and late adolescence (Silberg & Bulik, 2005; Klump *et al.*, 2007a). Further studies suggest that puberty moderates genetic effects on eating disorder symptoms, moving from no genetic influence in early puberty to significant genetic influence in mid- to post-puberty (Klump *et al.*, 2003, 2007b; Culbert *et al.*, 2009). These findings help to refine hypotheses regarding regulators of genetic effects, such as ovarian hormones activating genes of potential etiological significance during puberty (Klump *et al.*, 2008) and potential candidate genes (Klump & Culbert, 2007). However, it is unclear whether the magnitude of genetic influence remains stable from late adolescence through to adulthood, as further longitudinal data are not yet available (Klump *et al.*, 2010).

The genes most likely to be implicated in the heritability of eating disorders are within biological systems that relate to food intake, appetite, metabolism, mood, and reward-pleasure responses. However, this genetic influence is not attributable to any specific genes but rather is thought to result from a much more complicated interaction between genetic vulnerability and environmental factors. Molecular genetics studies aim to identify changes in DNA sequence and/or gene expression that may be involved in the pathogenesis of eating disorder symptoms and disordered eating behaviors, to uncover potential genetic variants that may contribute to variability of treatment response (see Zerwas & Bulik, 2011; Trace *et al.*, 2013).

Neurobiological and neuropsychological factors

Early neuroimaging studies of eating disorders in children and adolescents using single-photon emission computed tomography (SPECT) demonstrated hypoperfusion primarily in the temporal region of the brain (Gordon *et al.*, 1997). These findings were replicated (Chowdhury *et al.*, 2003) and found not to reverse with long-term weight restoration (Frampton *et al.*, 2011).

More recently, functional magnetic resonance imaging (fMRI) studies have shown that disordered eating may be a consequence of dysregulated reward and/or dysregulated awareness of homeostatic needs, possibly due to enhanced executive ability to inhibit incentive motivational drives, and the symptom expression of restricted eating may be a means of reducing negative mood caused by skewed interactions between serotonin aversive or inhibitory and dopamine reward systems (Kaye *et al.*, 2013).

A number of neuropsychological domains have been found to be impaired in those with eating disorders, including attention, memory, visuospatial processing, cognitive flexibility (set-shifting), impulsivity, and decision making. Most studies

have been conducted with adults and while findings can be contradictory, sample sizes are small and methodologies differ, some specific, subtle, cognitive impairments are emerging as being implicated in eating disorders. Although some impairments resolve with weight restoration, others appear to be a more trait-like phenomena, such as deficits in set-shifting (Roberts *et al.*, 2007). In children and adolescents, emerging research in this domain is less clear. For example, set-shifting has been found to be comparable in adolescents with AN and healthy controls (Fitzpatrick *et al.*, 2012) and in adolescents with BN and healthy controls (Darcy *et al.*, 2012). A recent large scale study assessed the neuropsychological profiles of children, adolescents, and young adults with eating disorders and found a pattern of strengths and weaknesses including good verbal fluency skills and poor visuospatial memory, associated with relatively weak central coherence (Stedhal *et al.*, 2012), although further research in this area is needed before conclusions can be drawn regarding the neuropsychology of eating disorders in children and adolescents.

Perinatal factors

Studies investigating perinatal influences as risk factors for the later development of eating disorders have consistently found an association. These factors are independent of sociodemographic confounders and contribute a 3.6% risk for AN (Lindberg & Hjern, 2003).

Obstetric complications have been found to be significant independent predictors of AN and BN, and the risk of developing AN increases with the total number of obstetric complications (Favaro *et al.*, 2006). These obstetric complications may contribute to impairment in neurodevelopment, which could be implicated in the pathogenesis of eating disorders.

Infection/illness triggers

There are a small number of cases in the literature suggesting in some instances that AN is triggered by infection (e.g., Sokol, 2000). The concept of pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) has been more widely studied in obsessive-compulsive disorder and tics/Tourette's syndrome (see Chapter 56). More recently, Swedo and colleagues (2012) proposed a broader category, Pediatric Acute-onset Neuropsychiatric Syndrome (PANS), the primary presenting clinical feature of which is acute and dramatic symptom onset of obsessive-compulsive disorder or severely restricted food intake. In utero exposure to viral infection has also been suggested as a risk factor for AN. In a population study, exposure during the sixth month of pregnancy to the peaks of chickenpox and rubella infections was significantly associated with an increased risk of developing AN (Favaro *et al.*, 2011).

Puberty

Connan *et al.* (2003) proposed a neurodevelopmental model of AN, which includes consideration of both the biological changes and the psychosocial transitions faced by young people as they go through puberty and how the rigidity of those vulnerable to

AN may be challenged by change, resulting in increased vulnerability to dysregulation in relevant biopsychosocial systems.

The onset of eating disorders is typically after puberty. Young people face many physical changes during pubertal development, for example, a rise in the average proportion of body fat and in body weight. Girls in middle childhood have a mean proportion of body fat of 8% and this rises to 22% after puberty and the period of maximum growth usually occurs between the ages of 11 and 13 years, during which time body weight rises by about 40% (Tanner, 1989). While boys also experience this weight gain, much of it is accounted for by an increase in muscle bulk. With regard to BN, both childhood obesity and early menarche, which in turn are often associated, are risk factors for the development of BN (Fairburn *et al.*, 1997).

Puberty onset is associated with profound changes in drives, motivations, psychology, and social life and these changes continue throughout adolescence. There are an increasing number of studies that have investigated the developing brain through adolescence, although these studies tend to define development by chronological age rather than pubertal stage. The few neuroimaging studies that have associated brain development with pubertal stage provide tentative evidence to suggest that puberty might play an important role in some aspects of brain and cognitive development (Blakemore *et al.*, 2010). How this may pertain to the development of eating disorders is yet to be elucidated.

Psychological factors

Psychodynamic theories

Early psychodynamic theories of eating disorders suggested that eating was equated with a wide range of factors such as gratification, impregnation, intercourse, performance, growing, and castration and with food symbolizing the breast, the genitals, feces, poison, a parent, or a sibling (Minuchin *et al.*, 1978). However, none of these theories accounted for the symptoms of AN, nor were they conducive to empirical testing (Goodsitt, 1985).

Palazzoli (1974) suggested a developmental object relations theory of the infant's progression through stages in relating to her mother, and Bruch (1973) hypothesized that refusal to eat and fear of fatness have their roots in early mother-child interactions, proposing that food refusal represents a struggle for psychological autonomy and control. Despite refined theories, psychodynamic therapies have not been adequately evaluated in the treatment of child and adolescent eating disorders and there is no evidence to support their efficacy.

Family theories

Minuchin *et al.* (1975) described the "psychosomatic family" in which the child's symptoms play an important role in maintaining the family's status quo and blocking change. Four key styles of interaction are characteristic of such families: enmeshment, overprotectiveness, rigidity, and conflict avoidance. Strober and Humphrey (1987) attempted to test these family styles of interaction experimentally. While they found that families with a child with AN tend to be out of touch with the child's

emerging affective needs, are less than optimally expressive in the emotional domain, and may reinforce control and restraint at the expense of autonomous self-expression, this did not validate the theory of a “psychosomatic family.” Similarly, Kog *et al.* (1987) found that while some families appeared to be a “close fit” to the model, others showed less extreme and even opposite kinds of family interaction. Eisler (1995) noted that families in which someone has an eating disorder are a characteristically heterogeneous group. In recent years, the emphasis on a family etiology has shifted toward an understanding of how the evolution of the family dynamics, in the context of the development of the eating disorder, may function as a maintenance mechanism (Eisler, 2005; Schmidt & Treasure, 2006).

Temperament

While no study has directly studied temperament as a risk factor for feeding disorder, studies have examined feeding difficulties in children. Feeding difficulties have been found to be more prevalent in children who are unsociable, difficult, or demanding (Hagekull *et al.*, 1997; Pliner & Loewen, 1997) and children with more emotional temperaments tend to display more food avoidant eating behaviors (Haycraft *et al.*, 2011). Childhood temperament (specifically higher levels of negative emotionality) has been linked to the development of later eating concerns (Martin *et al.*, 2000).

Certain temperament and personality traits have consistently been associated with eating disorders. Correlational research suggests that AN and BN are characterized by perfectionism, obsessive-compulsiveness, narcissism, sociotropy (concern with acceptance and approval from others), and autonomy (an orientation toward independence, control, and achievement), whereas impulsivity and sensation seeking are more typical of disorders characterized by bingeing (Cassin & von Ranson, 2005). While studies support the likelihood that neuroticism and perfectionism are risk factors for eating disorders, other temperament and personality traits that characterize eating disorders need further research to confirm their role as risk factors (Lilenfeld, 2011).

Attachment and trauma

Anxious insecure attachment styles are consistently found in adults with eating disorders (e.g., Illing *et al.*, 2010), and separation from mother and persistent maternal malaise during the first 5 years have been shown to be associated with later AN (Nicholls & Viner, 2009).

Early negative childhood experiences, including trauma and abuse are consistently found to be associated with BN and BED (Ericsson *et al.*, 2011; Groleau *et al.*, 2011). A recent meta-analysis of over 3 million psychiatric cases found that childhood sexual abuse was significantly associated with a lifetime diagnosis of an eating disorder (Chen *et al.*, 2010). Studies have also found a high incidence of unresolved trauma and loss in both those with eating disorders and their mothers (Fonagy *et al.*, 1996; Zachrisson & Kulbotten, 2006; Ringer & Crittenden, 2007).

However, there are significant methodological limitations in the literature in this domain, for example, inconsistent use of terminology and retrospective reporting, which makes it difficult to disentangle cause and effect.

Early feeding behavior

Longitudinal studies investigating the relationship between early feeding behavior and later eating disorders yield contrasting results. Marchi and Cohen (1990) found that pica, early digestive problems and efforts to restrict eating were linked to later bulimic symptoms, while picky eating and early digestive problems were associated with later anorexic symptoms. Kotler *et al.* (2001) found eating conflicts, struggles around meals, and unpleasant mealtimes were predictive of broadly defined AN, and that eating too little was found to be a protective factor for BN. This study found that picky eating was not associated with either later AN or BN, in contrast to Marchi and Cohen's (1990) findings.

In retrospective studies, higher rates of feeding problems, compared to controls, have been reported by mothers of children and adolescents with eating disorders (Jacobs & Isaacs, 1986; Rastam, 1992). However, another study has reported similar rates of feeding difficulties in adolescents with AN and controls (Shoebridge & Gowers, 2000).

As feeding is the result of an interaction between child and caregiver, feeding problems are usefully considered in this context. Children of mothers with an eating disorder scored higher on a measure of eating disorder psychopathology than control children, and their eating disturbance was associated with length of exposure to mothers' eating disorder and mother-child mealtime conflict at 5 years (Stein *et al.*, 2006). Maternal eating disorders have been found to increase the risk of childhood feeding difficulties and this association appears to be a direct effect of the maternal eating disorder mediated via maternal distress (Micali *et al.*, 2011) (see further Chapter 28).

Sociocultural factors

Although there seems to be general agreement that Western cultures put pressure on women to be thin and this contributes to the development of eating disorders, these disorders have been reported throughout medical history (Brumberg, 1988).

Cross-cultural research has been dominated by the assumption that Western values regarding thinness are responsible for the development of AN in non-Western contexts, but the empirical research does not corroborate this (Rieger *et al.*, 2000). However, media influences have been shown to affect increases in scores on an eating disorder questionnaire measure and increased incidence of self-induced vomiting following prolonged exposure to television in adolescent girls in Fiji (Becker *et al.*, 2002). Further research on both direct and indirect media influence on the development of eating pathology found that social network media exposure was associated with increased eating pathology in adolescent girls in Fiji (Becker *et al.*, 2011).

Significant relationships between perceived pressure to be thin and body dissatisfaction and dieting have been found in adolescents (e.g., Stice & Whitenton, 2002) and children (Field *et al.*, 2001).

Elevated dietary restraint has consistently been found to increase risk for onset of any eating disorder (e.g., Fairburn *et al.*, 2005) and adolescent females who report high dietary restraint have shown elevated risk for onset of threshold or subthreshold BN (Stice *et al.*, 2008). A meta-analytic review of risk factors for eating pathology highlighted the importance of factors associated with the “dieting domain.” These included family and personal history of obesity and critical comments from family members about weight, shape, and eating as being risk factors for the development of BN but not AN (Stice, 2002).

Weight concern as a risk factor for the development of eating disorders has been well replicated in the literature (Keel & Forney, 2013). Evidence from a recent prospective study found that body dissatisfaction was a strong predictor for onset of any eating disorder and that this risk was further amplified by higher levels of depressive symptoms (Stice *et al.*, 2011).

Adolescent girls reporting social pressure to be thin and body image preoccupation have shown a higher risk for onset of broadly defined BN or BED (McKnight Investigators, 2003), while those reporting weight and shape concerns and negative affectivity have shown a higher risk for future onset of broadly defined BN (Killen *et al.*, 1996).

Assessment

In view of the wide range of potential contributory factors and multiple pathways in the development of feeding and eating disorders, as well as varying levels of risk associated with the severity of the clinical presentation, it is important that assessment covers multiple domains. The adoption of a biopsychosocial framework for assessment and treatment is generally regarded as essential, and there is consequently a need to work in conjunction with other professionals, to include family medical practitioners and pediatricians. Table 71.2 summarizes the main recommended components of a comprehensive approach to assessment, which covers the full range of feeding and eating disorders. As can be seen, assessment needs to cover salient aspects of the child’s history, detail regarding the feeding or eating disturbance as well as the child’s current mental and physical state, and information about the child’s family and social context. Obtaining information relevant to the domains listed will allow the clinician to make a clinical diagnosis of any of the feeding and eating disorders mentioned earlier, as well as to determine level of risk. The three main areas of risk are in relation to physical state, psychological well-being and development. Identification of specific areas of risk will be key in prioritizing interventions.

Assessment and diagnosis will most usually be based on clinical interview involving discussion with the young person,

where the child is old enough and/or has the ability to provide relevant information, as well as information obtained from parents, caregivers or other adults (see Chapter 32). Children may not have the cognitive capacity to formulate and express the reasons behind their eating behavior. In AN or BN, the ability to articulate a fear of weight gain or the influence of body shape or weight on self-evaluation may not be present. Adult observation from parents, teachers, or others can be important in providing indirect evidence for weight or shape preoccupation and avoidance of weight gain. Physical examination and appropriate medical investigations are also important (see Chapter 35). For some presentations, direct observation of eating and mealtime behavior can also be extremely informative. For example, the behavioral component of rumination disorder can often be directly observed. The individual may contract tongue or abdominal muscles, cough, induce a retch or gag, and place a hand over the mouth in the process of regurgitating. Observation of feeding and mealtime interactions, aversion to food, fear responses, idiosyncratic eating behavior, and the presence of a sensory component to the presentation can usefully contribute to the clinician’s assessment of the nature and severity of the presenting disturbance.

Screening and assessment instruments

There are a number of standardized assessment measures relevant to the assessment of child and adolescent feeding and eating disorders and difficulties. These range from diagnostic assessment instruments delivered in an interview format, through self and parent report questionnaires to screening tools used in primary care settings. As with all such measures, they vary in terms of strengths and weaknesses and none comprehensively covers the full range of feeding and eating disorder presentations. There are very few detailed diagnostic measures available and some of the feeding and eating disorders lack detailed comprehensive assessment measures, in particular pica, rumination disorder and ARFID. This represents a problem for clinicians in relation to being able to recognize, diagnose, and plan appropriate interventions. The most widely used screening and assessment measures are listed in Table 71.3; helpful reviews of the various measures for use in child and adolescent populations can be found in Micali & House (2011) and Nicholson (2013). In addition to feeding and eating disorder specific measures, the clinician may choose to use broader measures covering multiple diagnoses such as the SCID (Structured Clinical Interview for DSM Disorders; First *et al.*, 1996), the DISC (Diagnostic Interview Schedule for Children; Shaffer *et al.*, 2000), or the DAWBA (Development and Well-Being Assessment; Goodman *et al.*, 2000), all of which include relevant sections.

Formulation and treatment planning

Having obtained information relating to the multiple domains described earlier, the clinician is required to evaluate and synthesize the information to allow diagnosis and appropriate

Table 71.2 Main components of comprehensive biopsychosocial assessment and relationship to risk.

Domain	Areas to cover in assessment
History	
Developmental	From birth, milestones, early feeding, speech and language, oral motor, sensory sensitivities, separation, social communication, relationships, play, character traits, behavior patterns
Feeding and eating	Onset of feeding/eating difficulties, relationship to weight/shape concerns, course, duration of current problems, key triggers
Medical	From birth, medical conditions and symptoms, operations, time off school because of illness
Significant events	Major personal and family life events, trauma, events having significant impact on individual
Current	
Feeding/eating behavior	Avoidance, restriction, self-feeding, binge eating, pattern of eating, speed of eating, eating in relation to hunger/satiety, solitary eating, eating nonfood substances
Behaviors associated with eating	Regurgitation, rechewing, spitting out, retching, gagging, vomiting, laxative (or other medication) misuse, exercise, behavior interfering with weight gain
Cognitions/emotions related to eating/weight/shape	Fear (distinguish between fear of weight gain/fat and fear of consequences of eating, e.g., vomiting), disgust related to food and own eating behavior, level of interest in food and eating, importance of shape/weight to self-worth, self-appraisal of body size and shape, understanding of current weight status, level of distress related to eating
Current intake	Range, nutritional breakdown, amounts, overall energy content, taken orally or enterally, intake defined by sensory characteristics (e.g., smooth, uniform color, regular appearance, etc.)?
Growth and development status	Weight, height, BMI centile (from BMI charts), weight loss/gain, faltering growth, pubertal delay, amenorrhea
Physical state	Pulse, blood pressure, electrolytes, minerals and full blood count, muscle strength, reflexes, concurrent medical conditions and symptoms. As indicated: dental exam (for enamel erosion resulting from vomiting), electrocardiogram, pelvic ultrasound, wrist X-Ray, DEXA (dual-energy X-ray absorptiometry)
Mental state	General mental state exam, comorbid diagnoses (e.g., depression, OCD, anxiety disorders, autism), insight, motivation to address eating difficulty
General functioning	Current developmental level, family relationships, peer relationships, school attendance and performance, engagement in activities, use of leisure time
Context	
Family/care environment	Family structure, adequacy of food availability, adequacy of appropriate caregiving, child's place of residence, social care involvement
Sociocultural background	Family, social and cultural practices around food and eating, weight and shape; values and attitudes influencing self-esteem
School	Ethos and expectations, mealtime arrangements, pastoral care arrangements, relationship between staff and parents
Main areas of risk	
Physical	Consequences of low weight/rapid weight loss; malnutrition; consequences of repeated rumination or purging behavior; poisoning; abdominal obstructions. NB: risk of death must be considered
Psychological	Suicide, self-harm, vulnerability to abuse
Developmental	Growth; bone age and density; puberty; cognitive; social, emotional, educational

treatment planning. This might include the need to consider the appropriateness of an admission or other high-intensity treatment option (see Chapter 50). Table 71.4 sets out common indicators for the clinician to consider in this respect.

As a result of the multifaceted nature of feeding and eating disorders, information about factors that may be maintaining the disorder can be helpfully integrated using a formulation approach. One model for a biopsychosocial formulation is that of the widely used “Five P’s approach” (Nicholson, 2013). Information obtained at assessment can be sorted into five sets of factors: presenting issues, predisposing factors, precipitating factors, perpetuating factors, and protective factors. Presenting issues and perpetuating factors form a natural focus for

intervention, utilizing where possible relevant positive factors. Risk, as discussed earlier and outlined in Table 71.2, will also be important in prioritizing interventions.

Treatment

Description of core principles and main treatment modalities

Treatment of feeding and eating disorders must take account of both physical and psychological aspects, as well as the systemic context of both family and school factors that may serve as protective and/or perpetuating factors, thus it is essential to

Table 71.3 Screening and assessment measures for child and adolescent feeding and eating disorders.

work in conjunction with other professionals including family medical practitioners and pediatricians. Teamwork and collaboration with parents in the treatment of feeding and eating disorders is essential (Lask & Bryant-Waugh, 2013).

Attention to physical and nutritional aspects may include pediatric and dietetic interventions to manage any medical problems resulting from the feeding or eating disorder and to restore a nutritionally adequate oral diet. In cases where the child or adolescent is underweight, restoration and maintenance of a healthy weight will be an important treatment component. Current practice varies widely in relation to rate of weight gain, but in general weekly gain of 0.5–1 kg is recommended as an aim

of treatment (National Institute for Health and Care Excellence (NICE), 2004). In severely malnourished patients, a more gradual increase of energy intake combined with regular physical monitoring to prevent the development of refeeding syndrome (typically characterized by fluid disorders such as edema and electrolyte disturbances, particularly hypophosphatemia) may be indicated (Katzman, 2005).

Medication has a limited role as first-line treatment for child and adolescent feeding and eating disorders. There is a very limited evidence base supporting the use of any pharmacological interventions with child and adolescent patients, and caution is needed in view of the physical vulnerability of this group (NICE, 2004). Nevertheless, drugs are used in practice albeit with uncertain effectiveness, most commonly SRRIs and antipsychotics, with main indications being depression, anxiety, and weight concern (Gowers *et al.*, 2010).

There is no one treatment of choice for feeding and eating disorders and often, combinations of treatment are recommended (NICE, 2004). The establishment of a therapeutic alliance is integral to successful outcome. In some instances, this can be challenging to establish; time spent assessing motivation and exploring perceived barriers or disadvantages to change can be helpful. Becoming stuck in therapy is often related to fear about change that may have been insufficiently explored or expressed. A brief outline of the three most commonly used psychological therapies in feeding and eating disorders is given in the following sections (see further Chapters 36, 38, 39, and 40).

Cognitive behavioral therapy (CBT) is an umbrella term used to describe therapies that share a theoretical basis in behaviorist learning theory and cognitive psychology, and which utilize methods of change derived from these theories. The focus of

these therapies is on the here and now and symptom reduction; some are more focused on behavioral interventions, where the objective is to identify and effect change in habitual behavior. Others are more focused on cognitive interventions, where the objective is to identify, monitor, and challenge dysfunctional, inaccurate, or unhelpful thoughts, assumptions, and beliefs that accompany difficult feelings and unhelpful behaviors. Thus, cognitive and behavioral principles can be applied across the entire range of feeding and eating disorders. CBT is case formulation driven, and the involvement and role of parents in the intervention may vary depending on the formulation.

Psychodynamic psychotherapy has been used widely in eating disorders and has the goal of enhancing the young person's ability to identify emotional states, develop a language of the emotions and communicate feelings and needs to others (Troup, 2013).

Family-based therapy (FBT) for eating disorders aims to enlist the parents as a resource in the practical resolution of the eating disorder, and takes an explicit agenda of blame reduction toward both the parents and the child. FBT assumes that resolution of the acute symptoms of the eating disorder and restoration of basic functioning need to be achieved before the young person will experience any relief from the cognitive symptoms, such as extreme weight and shape concerns. FBT consists of three phases. In the first phase, parents take charge of their child's eating, making decisions about appropriate eating as the young person is unable to engage in healthy eating behaviors. In phase two, when the young person has achieved more regulated eating and/or a healthier weight, control over eating is gradually handed back to the young person. Phase three attends to broader issues of family functioning and adolescent development.

Overview of current evidence base for treatment of feeding and eating disorders

There is minimal literature reporting psychological interventions for feeding problems and disorders in the absence of any known medical condition, with most reporting case study evaluations of interventions (Dovey & Martin, 2012). Children with feeding problems and disorders are a heterogeneous group and thus specific interventions have yet to be developed and disseminated. Few studies have used quantitative methods and all have evaluated different treatment approaches, such as treatment for food/choking phobia (Benoit & Coolbear, 1998), assessment of a parental educational program (Fraser *et al.*, 2004), and treatment designed to reduce caregiver stress (Greer *et al.*, 2008). A more recent study implemented a behavioral modeling intervention targeted at improving dietary variety and problematic mealtime behavior over a 16-week period, and found significant increases in the amount of foods accepted, increased weight, and a parent-reported decrease in mealtime problems (Dovey & Martin, 2012).

With regard to pica and rumination disorder, there are no published treatment trials, although the consensus in the literature is that both disorders can be treated using a behavioral approach (Williams & McAdam, 2012; Schroedl *et al.*, 2013). Similarly, little is currently known about effective treatment interventions for individuals presenting with ARFID, but the prominent avoidance behaviors characteristic of the disorder indicate that behavioral interventions, such as exposure and response prevention therapy, may be the best approach. Where there is an underlying emotional disturbance, such as anxiety or depression, CBT may prove to be an effective intervention (Kenney & Walsh, 2013).

While the evidence base for treatment of children and adolescents with AN is strongest for family interventions, this is still somewhat limited. There are only a small number of randomized controlled trials (RCTs), most of which had small sample sizes (Russell *et al.*, 1987; Le Grange *et al.*, 1992; Robin *et al.*, 1994; Eisler *et al.*, 1997; Eisler *et al.*, 2000; Lock *et al.*, 2005). Some, but not all, of these trials suggest that family therapy may be advantageous over individual psychotherapy in terms of physical improvement (weight gain and resumption of menstruation) and reduction of cognitive distortions, particularly in younger patients. While these studies provide the best evidence available for the treatment of AN in adolescents, the sample sizes in these studies are very low, with two studies having only 18 and 21 participants (Russell *et al.*, 1987; Le Grange *et al.*, 1992, respectively). In addition, the mean age of the study participants ranges from 14.2 years to 16.6 years, which means that the evidence base is for adolescents rather than for children.

Lock *et al.* (2010) conducted an RCT with a larger sample size ($n = 121$), comparing FBT with adolescent-focused individual therapy (AFT) in adolescents with AN and found no significant differences in full remission at the end of treatment. However, some differences that favored FBT at 6- and 12-month follow-up were found.

On balance, the evidence in favor of family therapy over individual therapy for adolescent AN is relatively weak. In the future, larger RCTs with long-term follow-up are required to assess whether family therapy is the most effective treatment for AN in adolescence.

Two studies have compared FBT with individual interventions in adolescents with BN. Schmidt *et al.* (2007) compared family therapy and CBT-guided self-care and found that CBT-guided self-care was superior to family therapy in reduction of binge eating behavior. LeGrange *et al.* (2007) compared FBT and supportive psychotherapy (SPT) and found significantly greater early reductions in symptomatic behavior for patients in FBT than in SPT. In addition, significantly more patients in FBT than in SPT remitted at end of treatment and at follow-up.

A recent review and meta-analysis of family therapy for both AN and BN concluded that behaviorally based FBT for adolescents with eating disorders is superior to individual therapy at 6–12-month follow-up, although there is no difference at end of treatment (Couturier *et al.*, 2013).

While there is some support for individual CBT approaches in adolescents with BN and other binge eating syndromes (e.g., Schmidt *et al.*, 2007), and more recently for CBT-E in adolescents with AN (Dalle Grave *et al.*, 2013), the evidence base for CBT for AN in adolescents is very much in its infancy. Nevertheless, eating disorders represent a good example of how abnormal thoughts and behaviors combine to result in physical and social impairment and thus, in theory, cognitive behavioral approaches could provide an effective strategy for treating these disorders (Gowers & Green, 2009). Further research is necessary in order to explore this idea.

Limitations in the quality of the evidence base in child and adolescent feeding and eating disorders

Greater effort is needed to improve the quality of treatment studies conducted in child and adolescent patients with eating disorders. Only three of the studies discussed earlier (Lock *et al.*, 2005, 2010; Schmidt *et al.*, 2007) could be considered to be of sufficient quality to provide a solid evidence base.

Studies have also been hampered by a number of methodological limitations. While additional and larger clinical trials are currently being undertaken, they focus exclusively on AN and BN, usually in adolescents. One problem in evaluating treatment efficacy in children is the low base rate of AN and BN in children. Eating disorder definitions in both DSM and ICD classification systems have failed to capture the majority of eating disorders that appear in children (Nicholls *et al.*, 2000). The advent of DSM-5, which contains significant changes to the diagnoses of feeding and eating disorders, is predicted to capture more childhood presentations, which in turn will facilitate the evaluation of treatment efficacy in this population. To date, there have been no controlled treatment studies of conditions other than AN and BN in adolescents, which brings to mind the adage “we study what we define” (Walsh & Kahn, 1997); this may have a particularly deleterious effect on developing evidence-based treatments for feeding and eating disorders in children and adolescents.

Often, treatment studies have used nonstandardized therapies, which limit opportunities for comparison and replication and also the potential for clinicians to implement these therapies in their own practice.

Many controlled treatment studies exclude boys from participation. However, the lower base rate of eating disorders in boys makes it difficult to recruit adequate numbers to establish gender differences in treatment efficacy. Because eating disorder interventions have been designed, refined, and tested predominantly in female participants, it remains unclear whether these treatments are useful in treating boys with eating disorders.

Most controlled treatment studies in adolescents provide no information concerning the ethnic/racial diversity of participants. In those that do, ethnic minority representation appears to be a function of the geographic locations in which research has been conducted, and analyses of differential treatment

completion or response are not presented. Thus, the question of whether ethnicity/race serves as a moderator variable cannot be answered.

In summary, the evidence base for psychological treatments for eating problems in children and adolescents is quite limited. As a consequence of the small number of studies and methodological limitations in existing studies, it is not possible to describe in any detail what treatments work for whom.

Consent and ethical issues

Eating disorders are unusual among presentations in child and adolescent psychiatry in that they are potentially life threatening and may have very serious physical and psychosocial consequences if effective treatment is not provided. Given that young people with eating disorders are often reluctant to seek or accept treatment, practitioners need effective ethical and legal guidelines in order to make treatment decisions (Foreman, 2006).

All possible attempts should be made to form a therapeutic alliance with the young person, both to achieve consent to treatment on ethical grounds, and because therapeutic alliance is associated with effectiveness of treatment. In England and Wales, parents or those with parental authority may consent on their children's behalf up to the age of 18 but different countries operate different age limits. While it is desirable to obtain the young person's consent, it is helpful to make a distinction between treatment directed at reducing risk from the physical consequences of the eating disorder and psychological treatment of the eating disorder. The decision to treat against the young person's wishes is usually most likely to arise when hospital admission is indicated and the young person declines treatment. However, the decision to treat a young person against their will should always be considered a last resort.

Legislation differs between countries, although similar principles apply when deciding which approach to take. Parental consent to treatment is often the most appropriate choice, particularly in the short term and for younger patients, as often young people will engage with treatment once they feel safe within the treatment setting. If the young person consistently continues to decline treatment, leading to the need for active treatment against their will (e.g., nasogastric feeding) and/or absconding, using mental health legislation to provide the basis for treatment should be considered (see further Chapter 19).

Outcome

Outcome studies can generally be divided into two categories: those that attempt to establish the efficacy of a particular treatment (see section on Treatment in this chapter) and those that attempt to establish prognostic factors.

Problems in outcome research

There are a number of methodological shortcomings in the outcome literature in this field, including small sample sizes, inadequate measurement of target symptoms, failure to use

standardized assessment measures, inadequate follow-up, high attrition rates, and variability in the definition of remission and recovery. While for adults, recovery implies restoration to premorbid physical and mental health, for children and adolescents, recovery includes rejoining a normal developmental trajectory, which will involve facing a number of physical and social aspects of identity that have not yet been experienced (Gowers, 2013).

Prognostic factors

Generally, for every study that identifies a group of prognostic factors, another study will fail to replicate the significance of the group of variables identified. These inconsistencies and contradictions can be accounted for by methodological flaws as noted earlier. Nevertheless, age at onset, duration of inpatient care, comorbidity, and social problems have been identified as important prognostic factors (Lowe *et al.*, 2001; Finfgeld, 2002; Steinhausen, 2002).

Recovery and remission

Outcome studies fairly consistently report that 47–57% of children and adolescents with eating disorders recover, 29–34% improve, and 17–20% follow a chronic course (e.g., Fisher, 2003; Halvorsen *et al.*, 2004). In general, remission rates increase with longer duration of follow-up for all diagnoses (Keel & Brown, 2010). It is often difficult to generalize findings from studies of outcome of eating disorders as there is wide variation in the outcome parameters used across studies. Remission rates in AN appear to vary depending on where the sample was drawn from and in adolescents treated in the community, relatively high rates of remission have been found at five year follow-up (76%) and eight year follow-up (82%) (Clausen, 2008). Rates of remission for BN do not appear to vary depending on where the sample was drawn from, with no apparent differences between rates of remission for adults and adolescents or for inpatients and those treated in the community. Remission rates for BN remain stable at around 70% or higher in samples followed up between 5 years and 20 years after baseline assessment (Keel & Brown, 2010).

Several outcome studies of EDNOS have looked at remission in the context of bulimic type symptoms and have compared the outcome of those with EDNOS to those with BN. Remission rates for adolescents with EDNOS appear to be higher than for those with BN following treatment (Schmidt *et al.*, 2008). However, remission rates for EDNOS and BN do not differ significantly at five year follow-up, with both having remission rates of about 75% (Grilo *et al.*, 2007). Similar rates of remission are found in EDNOS (75%) and BN (72%) at 20-year follow-up (Keel *et al.*, 2010).

With regard to treatment setting, Gowers *et al.* (2007) found that neither psychiatric inpatient nor specialist outpatient treatment provided better outcomes than nonspecialist outpatient treatment for adolescent AN. Inpatient treatment (randomized or after outpatient transfer) predicted poor outcomes. However,

adherence to inpatient treatment in this trial was less than 50%, which may have compromised the effectiveness of this treatment. Further studies are needed in order to clarify optimum treatment options.

Migration between diagnoses

Those with AN who do not achieve remission over the course of follow-up often develop either BN or EDNOS. However, those with BN who do not achieve remission over the course of follow-up usually continue to meet full criteria for BN or transition to a diagnosis of EDNOS, including BED, with crossover to AN from BN being particularly rare (Keel & Brown, 2010).

Prevention

Much of the work on eating disorders prevention has been conducted within school settings, mostly in the form of the evaluation of specific preventative programs delivered in classroom settings. These have delivered mixed findings with no one clearly superior program. The impact of such interventions on incidence of eating disorders is hard to ascertain and it is generally recognized that such initiatives can only ever form part of a comprehensive preventative approach, which also requires family and societal components as well as improved understanding of the complex etiological pathways of eating disorders.

Conclusion

This chapter summarizes current knowledge, understanding, and practice in feeding and eating disorders in children and adolescents. The implications for clinicians and their patients of recent changes in DSM-5 and proposed changes in ICD-11 (Uher & Rutter, 2012) will unfold over the coming years. It is hoped that improved recognition, greater consistency in use of terminology, enhanced knowledge and understanding in the areas of epidemiology and etiology and the development of more effective interventions will follow. There is undoubtedly still a long way to go in improving the quality and consistency of care for children and adolescents with significant eating difficulties. It is unclear whether current approaches to classification in the form of categorical diagnostic groups will prove most useful in the long term as basis for research endeavors. Developments in cross-cutting dimensional research, such as initiatives attempting to classify psychopathology based on dimensions of observable behavior and neurobiological measures (Cuthbert & Insel, 2013) may in due course result in more meaningful, useful, and effective changes in how we develop and select appropriate treatments for our patients.

CHAPTER 72

Somatoform and related disorders

M. Elena Garralda¹ and Charlotte Ulrikka Rask²

¹Academic Unit of Child and Adolescent Psychiatry, Imperial College London, UK

²The Research Clinic for Functional Disorders and Psychosomatics, Regional Centre for Child and Adolescent Psychiatry, Aarhus University Hospital, Aarhus, Denmark

Characteristics of the disorders and classification

The essential feature of somatoform disorders as described in the World Health Organization (WHO, 1992) and the Diagnostic and Statistical Manual of Mental Disorders (DSM) classificatory systems (WHO, 1992; American Psychiatric Association, 1994, 2013) is the presence of physical symptoms that cause concern and are not explained by a general medical condition or psychiatric disorder. Symptoms must lead to noticeable and significant distress or impairment in social (family and friends) and occupational spheres of functioning, which in children means school and academic difficulties. The symptoms are not feigned and usually occur in association with emotional conflict or psychosocial stress. In rare cases, the associated impairment may be extreme and result in states of severe or pervasive withdrawal when children stop communicating, walking, and looking after their basic needs.

Conversion/dissociative disorders share the main features of the somatoform disorders, but differ from them in that the main presentation is symptoms specifically affecting the motor and sensory systems. Nevertheless, because of their closeness to somatoform disorders, they and other related problems such as chronic fatigue syndrome (CFS) and juvenile fibromyalgia will be outlined in this chapter.

Somatoform disorders present predominantly in older children and adolescents, but early manifestations can be identified in younger preschool children. The diagnosis often relies on dual pediatric medical and psychiatric assessments and can therefore be more complex than that of other purely psychiatric or medical disorders.

We will describe how to differentiate somatoform disorders from physical complaints in healthy children, outline the concept of somatization, the classification of somatoform disorders in International Classification of Diseases (ICD-10) and in the

recently published DSM-5 classificatory systems, as well as the uses of a dimensional approach. We will address clinical presentations, developmental issues, assessment and diagnosis, aetiology, risk factors and treatment.

Throughout the chapter, key abbreviations are *FSS* for functional somatic symptoms *RAP* for recurrent abdominal pains, *CFS* for chronic fatigue syndrome and *CBT* for cognitive behavioral therapy.

The experience of somatic symptoms in children and young people

Somatic symptoms are part of everyday life experience in children and young people (Offord *et al.*, 1987; Garber *et al.*, 1991; Eminson *et al.*, 1996; Domenech-Llaberia *et al.*, 2004; Rask *et al.*, 2009b). These symptoms are mostly “functional” rather than “organic” (i.e. the expression of a medical disorder) and reflect common non-pathological or physiological bodily changes. In contrast with somatoform disorders, most functional somatic symptoms (FSS) in healthy children are neither persistent nor impairing, they tend to be ascribed to non-medical everyday biological or psychological stress and do not lead to medical help seeking (Huang *et al.*, 2000; Rask *et al.*, 2013a).

The concept of somatization

The concept of somatization is central to understanding the psychological ramifications of FSS and of somatoform and related disorders. The term has gained currency to describe a constellation of clinical and behavioural features involving: first, a tendency to experience and communicate distress through somatic symptoms unaccounted for by pathological findings; secondly these symptoms are attributed to physical illness and thirdly they lead to seeking medical help (Lipowski, 1988). In this review, we will describe FSS and somatoform and related disorders likely to be an expression of psychological distress and of somatization, even if these symptoms and disorders can also reflect bodily vulnerabilities.

The current classification of somatoform and related disorders

Current ICD and DSM classification systems diagnose disorders categorically. In ICD-10, somatoform disorders are a sub-category (coded F45) of the broader “Neurotic, stress disorders and somatoform disorders”. Among its various sub-divisions, persistent somatoform pain disorder is most commonly observed in children and young people, while the diagnostic criteria for somatization disorder and hypochondriasis are seldom fully met in this age group.

Closely related clinical problems, also with somatization at their core, are classified in ICD-10 under the same broad grouping but as a separate dissociative (conversion) sub-category (code F44), the main complaint being medically unexplained neurological sensory or motor symptoms, such as paralysis, abnormal gait, loss of sensation, or pseudo-seizures. Presentations with fatigue as a main symptom are diagnosed as neurasthenia (F48). This term is now out of favour, but is descriptively close to clinical problems referred to in the research literature as CFS and CFS-like disorders, which also share the key features of the somatoform disorders.

Comparatively short-lived episodes with key somatoform features may be diagnosed as “adjustment disorders” if they follow closely on the experience of a marked and universally stressful event.

In DSM-5, somatoform disorders are referred to as “somatic symptom and related disorders”, and the number of sub-categories has been substantially reduced (somatization disorder, hypochondriasis, pain disorder and unspecified somatoform disorder are no longer included). The category does include “psychological factors affecting other medical conditions” and “factitious disorder” as well as conversion disorder, now referred to as “conversion disorder (functional neurological symptom disorder)”. Individuals with high health anxiety levels without somatic symptoms will receive a diagnosis of “illness

anxiety disorder” unless the health anxiety is explained by a primary anxiety disorder, such as generalized anxiety disorder.

There is lack of clarity about the extent to which the essence of somatoform disorders lies in the functional or medically unexplained nature of the symptoms or in the distress/impairment caused (Dimsdale & Creed, 2009; Fink & Schroder, 2010). In DSM-5 (and probably also in the forthcoming ICD-11), the disorders are defined on the basis of positive symptoms, namely distressing somatic symptoms together with abnormal thoughts, feelings and behaviours in response to these symptoms. This might help improve the present situation where the same FSS are classified in medical and pediatric clinics as functional (non organic) disorders, but as somatoform disorders in psychiatric clinics. Table 72.1 provides examples of overlapping diagnostic labels in different specialties. Nevertheless in DSM-5 medically unexplained symptoms remain a key feature of conversion disorder, because it is possible to demonstrate definitively in such disorders that the symptoms are not consistent with medical pathophysiology.

The dimensional perspective

A categorical conceptualization is appropriate for somatoform disorders at the severe end of the spectrum (Figure 72.1). However, the dimensional perspective is useful in clarifying the significance of somatic symptoms in general populations or those attending primary health care and other medical clinics. In addition, while the categorical framework is appropriate for school children and adolescents, it is rare for young preschool children to have complaints that are severe and impairing enough to reach the diagnostic threshold for somatoform disorders: a dimensional perspective is more appropriate in this age group.

Developmental aspects

Key components of the somatoform disorders are not readily expressed by young preschool children as they do not have the

Table 72.1 Different terms and diagnostic labels used for somatoform and related disorders according to medical specialty.

Specialty	Somatoform and related disorders
Child and adolescent psychiatry	Adjustment disorder, somatoform disorder, conversion/dissociative disorder, neurasthenia, pervasive refusal (withdrawal)
Pediatric rheumatology	Juvenile fibromyalgia, chronic benign pain syndrome, growing pains
Pediatric cardiology	Non cardiac chest pain
Pediatric gastroenterology	Functional abdominal pain conditions (Rome III criteria): childhood functional abdominal pain, childhood functional abdominal pain syndrome, abdominal migraine, irritable bowel, functional dyspepsia, cyclic vomiting syndrome
Pediatric infectious medicine	Chronic fatigue syndrome, myalgic encephalomyelitis
Pediatric respiratory medicine	Hyperventilation syndrome
Pediatric neurology	Tension headache, pseudo-epileptic seizure
Ophthalmology	Non organic visual loss, amblyopic school girl syndrome

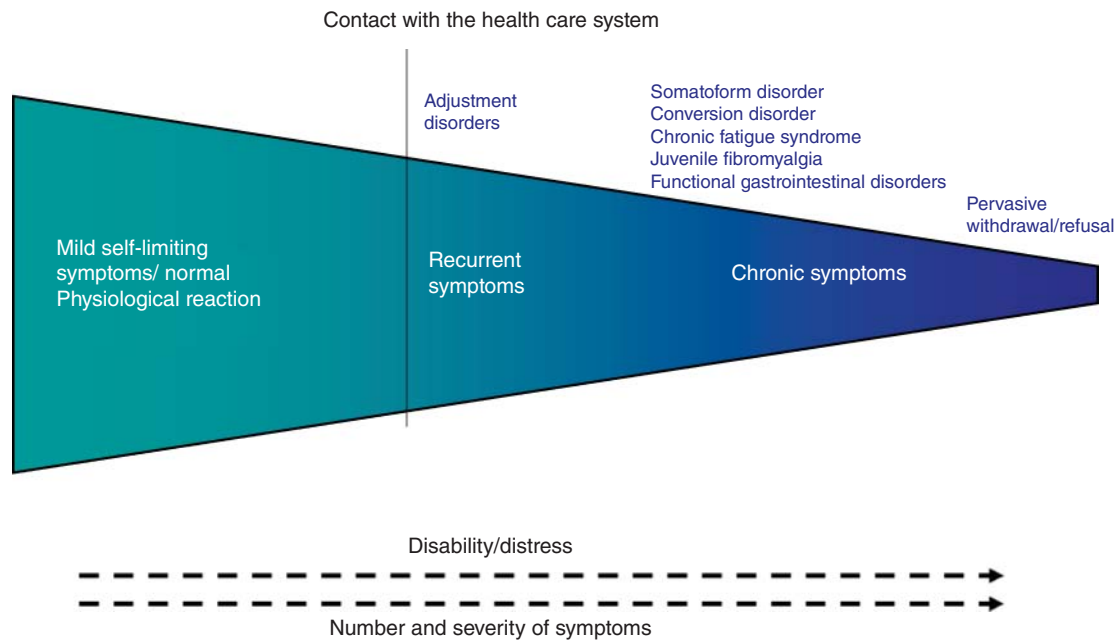

Figure 72.1 The spectrum of functional somatic symptoms and somatoform and related disorders.

necessary experience and knowledge to articulate illness beliefs, and medical help seeking is a parental activity well into adolescence. However, parental-reported symptoms suggestive of somatization have been reported in children as young as 5–7 years (Rask *et al.*, 2009b, 2012).

Somatization-related disorders in young children although based on complaints by the children themselves are primarily manifested through parental concerns, beliefs and behaviours. Excessive unreasonable parental concern about children's FSS, when linked to illness conviction and repeated medical help-seeking, can lead to unnecessary assessments and treatments, some of which may be potentially damaging and compromise the child's physical and mental health. This may be conceptualized as parental somatization and raises the question whether the diagnosis in some cases should be a parental psychiatric one within the spectrum of factitious illness or Munchausen by Proxy (Eminson & Postlethwaite, 1992).

Clinical presentations, assessment and diagnosis

Clinical presentations

Typical presentations in children are (i) pain, most commonly with recurrent episodes of severe abdominal pain, headaches, or other pains which occur at least monthly and often weekly or daily; (ii) fatigue/exhaustion—severe and incapacitating lasting at least 3 months and often over 6 months and (iii) loss of the ability to carry out usual bodily movement, loss of sensory perceptions and/or pseudo-seizures.

Characteristically, *functional abdominal pain* (FAP) presents as intense, recurrent, diffuse, or peri-umbilical, often worse in

the day, less prominent at nights or in school holidays. It may be accompanied by vomiting, headache and lethargy and the child may look pale and unwell, which can reinforce family beliefs of an organic pathology. Headaches are more likely than not to be characterized as tension headaches (frequent, bilateral, typically frontal, “like a band”), but they do sometimes coexist with migraine attacks (a periodic, severe, unilateral pain with an accompanying aura, nausea and a similar family history). Commonly, there are additional complaints of other less prominent physical symptoms—multi-symptomatic presentations being habitual in clinical settings—as well as mood changes and marked impairment with reduction in social contact with peers and school absence.

Attempts have been made by gastroenterologists to subdivide the group of children with unexplained gastrointestinal symptoms into specific symptom patterns such as vomiting, defecation and pain in accordance with the Rome Criteria (Rasquin-Weber *et al.*, 1999). However, the validity and reliability of these sub-groupings are not well established (Chogle *et al.*, 2010) and only a subset of children reporting abdominal pain fulfil the Rome criteria for “abdominal-pain related functional gastrointestinal disorders” (or FGIDs) (Saps *et al.*, 2012).

Juvenile fibromyalgia is a functional medical disorder descriptively close to the somatoform pain disorders. It is defined as a chronic pain condition of unknown aetiology, primarily distinguished by wide spread musculoskeletal pain, sleep difficulty, depression and fatigue (Anthony & Schanberg, 2001). There are no objective signs of arthritis and normal laboratory tests.

The key features of CFS include severe disabling physical and mental fatigue and exhaustion after minor effort, not relieved by rest, of at least 6 months duration (although 3 months is

regarded as more appropriate for children), accompanied by marked functional impairment and often headaches and sleep disruption, muscle or other pains and mood changes. It commonly starts with an acute flu-like illness or glandular fever, but the onset may also be gradual and fluctuating. Many children complain of sore throats, which may be accompanied by lymph node tenderness, anorexia, nausea and dizziness (Garraalda & Chalder, 2005).

Conversion/dissociative disorders involve partial or complete loss of bodily sensations or movements. In children, loss or disturbance of motor function and pseudo-seizures are most common, but other presentations are loss of sight, hearing, sensation, consciousness, fugue or mutism. Symptoms are often brought on by a traumatic trigger and remit after a few weeks or months (Ani *et al.*, 2013).

Hypochondriasis, or health/illness anxiety involves persistent preoccupation with fears of having a serious illness, based on the misinterpretation of bodily sensations believed to be indicative of serious disease and persistent seeking of medical reassurance. It has been suggested that hypochondriasis has primarily an onset in adulthood, but evidence is now emerging that cognitive and behavioural features similar to those described in adults are also present in children and adolescents (Wright & Asmundson, 2003; Rask *et al.*, 2012).

Associated impairment

Symptom-related impairment is a key feature of the somatoform disorders and multi-symptomatic complaints and is observed in community samples of children as young as 5–7 years as well as in adolescents (Rask *et al.*, 2009b; Vila *et al.*, 2009). Impairment can involve prolonged periods of withdrawal from social relationships and school absence, lasting for months or years, potentially restricting opportunities for the development of social skills and academic advancement (Rangel *et al.*, 2000b; Smith *et al.*, 2003; Garraalda & Rangel, 2004). Uncommonly children become wheelchair- or bed-bound, unable to communicate and look after their basic needs (Garraalda, 1992a; Thompson & Nunn, 1997; McNicholas *et al.*, 2013).

Pathways and engagement in mental health referral

Most children with recurrent somatic complaints will be known to their general practitioners or family doctors and be referred by them in the first instance to their local pediatric clinic. For many children, a pediatric assessment will be sufficient to clarify the nature of the problem and lead to a resolution.

It is, of course, important and indeed essential that the appropriate physical examinations are conducted to exclude a treatable medical disorder. However, there is also a danger—especially in the more severe cases—of over-investigating medically. In the absence of organic indicators, these over-investigations are thought likely to be unproductive, potentially harmful as well as non-cost-effective (Lindley *et al.*, 2005; Dhroove *et al.*,

2010) and they can delay addressing the potential underlying psychosocial aspects.

A psychiatric opinion is important for differential diagnosis, to confirm or exclude the presence of a somatoform or related disorder and of co-morbid psychiatric disorders amenable to psychiatric intervention. It should also be helpful in identifying biopsychosocial factors likely to play a part in symptom maintenance and to put into place a programme of psychiatrically informed psychosocial rehabilitation.

The mental health assessment will require specific skills in medical/psychiatric differential diagnoses, liaison with pediatric services, prioritizing family engagement in assessment and treatment and helping families move from a purely physical to a biopsychosocial framework, crucially *at a pace* that is appropriate and acceptable to them. These skills are usually available to pediatric liaison teams see Chapters 32 and 42.

Diagnosis, differential diagnosis, and psychiatric comorbidity

In accordance with criteria for other psychiatric disorders, diagnosis is determined by the severity, distress and impairment caused by the symptoms, and more specifically by illness behaviours, concerns or beliefs in the absence of an identifiable medical disorder and despite a reasonable medical explanation. A diagnosis of a somatoform or related disorder should be considered when there is a time relationship between a psychosocial stressor and the somatic symptoms (i.e. when stressors are closely related in time to or precede the onset of physical symptoms) and when the nature and severity of the symptom(s) and related impairment are out of keeping with the pathophysiology.

The nature of the somatic symptoms is an important guide for diagnosis and for the decision to investigate medically. In recurrent abdominal pains and in the absence of organic indicators, some authors recommend a coeliac disease screen as the only investigation worth carrying out (Wright *et al.*, 2013).

Somatoform and conversion disorders may sometimes develop in the context of an organic medical problem. A child with inflammatory bowel disease may display symptoms, distress and impairment that do not correspond to or far exceed what may be expected from other children and young people with comparable illness levels (Garraalda, 1992b); or a young person with epilepsy may have “pseudo-seizures” outside the range of epileptic phenomena, alongside medically recognizable epileptic ones (Patel *et al.*, 2011).

FSS and somatoform disorders should be differentiated from malingering or the intentional production by the child of false or grossly exaggerated symptoms in order to achieve privileges. Childhood illness can have clearly desirable consequences—including increased parental attention and care and legitimate withdrawal from difficult situations—and the child is in a strong position to modulate and control

the consequences. Not surprisingly, therefore, a spectrum of intentionality is to be expected and should be duly evaluated in somatoform disorders. It is, however, not helpful for this intentionality to be exposed, unless it is gross and the predominant feature of the presentation.

Somatic symptoms are commonly reported as part of anxiety and depressive disorders, but unlike in somatoform disorders, they are not the main focus of concern. However, psychiatric disorders—usually anxiety and depressive disorders—are a common comorbidity. In a study of children with recurrent abdominal pains attending pediatric clinics, three quarters were found to have a comorbid anxiety disorder (Campo *et al.*, 2004a) and psychiatric disorders had been present in the 12 months before the assessment in three quarters of young people with CFS attending specialist clinics (Garraalda *et al.*, 1999). Comorbid psychopathology is reported in a quarter to half of the children with conversion disorders seen in specialist services (Pehlivanurk & Unal, 2000; Ani *et al.*, 2013).

The high levels of comorbid anxiety and to a lesser extent depressive disorders in childhood FSS and somatoform disorders, the fact that comorbid anxiety and depression are linked with the number of somatic symptoms, the strong and reciprocal associations between somatic and mood symptoms across the life span have led some authors to question the separate classification of these disorders and to call for research to clarify the nature of these interactions (Campo, 2012).

Epidemiology

Knowledge of the epidemiology of somatoform and related disorders and symptoms is critical to develop an appreciation of their public health implications and to optimize health care planning. However, there are two major barriers in the epidemiological field of these disorders. The first is case definition. This is a special problem in younger children as even though clustering of different types of somatic symptoms has been shown in preschool and early primary school children (Domenech-Llaberia *et al.*, 2004; Rask *et al.*, 2009b) developmental immaturity prevents their full syndromic manifestation. Furthermore, the current fragmented clinical approach with the use of various diagnostic labels as illustrated in Table 72.1 can be an obstacle to research in clinical populations.

The second barrier is case ascertainment. The requirement of a physical examination to establish the lack of an explanatory medical diagnosis and of links with stressors poses methodological problems in large community studies, the majority of which have simply used self- or parent-report somatic symptom questionnaires. In most children and adolescents, FSS will be short-lived with no negative long-term impact on daily functioning or developmental course and inclusion of symptom-related impairment criteria, therefore, decreases prevalence estimates substantially.

Thus, prevalence estimates vary considerably due to different case definitions, assessment instruments and study populations. Table 72.2 outlines results of population-based studies which have assessed a variety of somatic complaints/FSSs.

On balance, prevalence rates based on studies attempting to cover the whole spectrum of FSS, symptom-related impairment as well as medical information about actual physical health, suggest that 4–10% of children and adolescents in the general population are substantially affected and likely to be in need of a clinical intervention, the higher rates being found among older children and adolescents. In general, symptoms are also more prevalent in girls. Complaints lead to medical consultation in approximately a third of cases—possibly depending on symptom severity and impairment and on familiar health care seeking patterns (Huang *et al.*, 2000; Perquin *et al.*, 2000; Rask *et al.*, 2013a).

Functional or recurrent abdominal pain is the most investigated single somatic symptom. It affects 7–25% of school age children and accounts for more than 50% of consultations in pediatric gastroenterology (2–4% of all general pediatric office visits) often incurring high medical costs (Dhroove *et al.*, 2010). Cross-sectional studies in Nordic countries suggest that the prevalence of self-reported somatic symptoms such as frequent headache and abdominal pain in children has increased during the past decades (Berntsson & Kohler, 2001; Santalahti *et al.*, 2005), but whether this has led to a higher use of health care sources has not been documented.

Prevalence rates of somatoform and related disorders

Very few large-scale studies have been conducted in younger populations to examine the prevalence of somatoform disorders following DSM or ICD diagnostic criteria. Two large German population-based adolescent surveys assessed the prevalence of somatoform syndromes and disorders through the use of highly structured interviews incorporating DSM-IV diagnostic algorithms; they reported lifetime prevalence rates of 12–13% (Essau *et al.*, 1999; Lieb *et al.*, 2000). However, in the study of 14–24-year-olds by Lieb *et al.*, this was mainly accounted for by undifferentiated somatoform/dissociative syndromes. Specific disorders were considerably less common, the lifetime prevalence of specific pain somatoform disorders being 1.7% (12-month prevalence of 0.9%).

With regard to functional unexplained gastrointestinal symptoms defined according to Rome criteria, a cross-sectional community study reported rates of irritable bowel syndrome (IBS) in 14% of high school and 6% middle school students (Hyams *et al.*, 1996). CFS-like problems have been identified in some 2–4% of 5–17-year-olds or adolescents in the United States and United Kingdom (Garraalda & Chalder, 2005; Viner *et al.*, 2008; Crawley *et al.*, 2012), but only 0.2% of adolescents in the general population meet criteria for full CFS (Chalder *et al.*, 2003). Prevalence rates of juvenile fibromyalgia of 6% have

Table 72.2 Selected population-based studies that have assessed different types of somatic complaints/functional somatic symptoms (FSS).

Reference/country	Symptoms	N/age	Prevalence/time frame
Offord <i>et al.</i> (1987) Canada	Combination of possible unexplained symptoms, loss of function and health concerns	N = 2674 4–16 yrs	Somatization ^a /past 6 months 4–11 yrs: not measurable 12–16 yrs: ♀: 10.7%, ♂: 4.5%
Garber <i>et al.</i> (1991) United States	35 symptoms	N = 540 “school-aged”	Symptoms/past 2 weeks ≥4 symptoms: 15.2%, ≥13 symptoms: 1.1% ♀ > ♂ in high school students. No gender difference in younger age groups
Perquin <i>et al.</i> (2000) Holland	Pain (locations: head, abdomen, limb, ear, throat, back or elsewhere)	N = 5423 0–18 yrs	Chronic pain/past 3 months Total: 25.0%, ♀ > ♂ 0–3 yrs: 11.8%, ♀ < ♂ 4–7 yrs: 19.3%, ♀ > ♂ 8–11 yrs: 23.7%, ♀ > ♂ 12–15 yrs: 35.7%, ♀ > ♂ 16–18 yrs: 31.2%, ♀ > ♂ Multiple chronic pain: 12.9%
Berntsson & Kohler (2001) Nordic countries	Stomach complaints, headache, sleeplessness, dizziness, backache, loss of appetite	N = 3812 7–12 yrs	Any symptom: 25.0%/not stated, ♀ > ♂ Mild: 16.7% Moderate: 7.5% Severe: 0.8%
Domenech-Llaberia <i>et al.</i> (2004) Spain	Abdominal pain, leg pain, headaches, tiredness, dizziness	N = 807 3–5 yrs	≥Four times complaints/past 2 weeks: 20.4% Frequent complaints associated with more pediatric consultations and absence from preschool. No gender difference
Vila <i>et al.</i> (2009) United Kingdom	35 symptoms	N = 1173 11–16 yrs	Symptoms/past 2 weeks ≥1 symptom: 37%, ≥4 symptoms: 12% ≥7 symptoms: 4%, ≥13 symptoms: 0.8% ♀ > ♂ At least 10% associated impairment (reduced ability to concentrate, enjoy activities, go to school, see friends)
Rask <i>et al.</i> (2009) Denmark	20 symptoms	N = 1327 5–7 yrs	One-year prevalence of FSS ^b FSS overall: 23.2%, ♀ > ♂ Impairing (distress, interference with social life, high use of health services and/or absence from school/day care) FSS: 4.4%, no gender difference Multiple FSS: 9.3%

FSS: functional somatic symptoms.

^aCase definition: distressing recurrent somatic symptoms with no known organic cause and perception of oneself as sickly.

^bAssessment by layman administered parent interview (SAI) with subsequent clinical rating of information.

been reported in a population-based sample of 9–15-year-olds (Buskila *et al.*, 1993).

The prevalence of hypochondriasis or health anxiety in childhood is unknown. This may be related to the lack until recently of relevant screening tools (Wright & Asmundson, 2003).

Prevalence rates of dissociative/conversion disorders

The incidence of dissociative or conversion disorders has been studied through surveillance studies of new cases reported by pediatricians and child psychiatrists in Australia and the United Kingdom, yielding low yearly incidence rates of 1.30 and between 2.3 and 4.2 per 100,000, respectively (Ani *et al.* 2013; Kozłowska *et al.*, 2007). Conversion is rarely identified in

children below 7 years, the incidence increasing with age and with a female preponderance.

Cultural aspects

The literature suggests variations in the types of somatoform clinical presentations in different cultural areas. The incidence of conversion disorders appears high in children attending Indian outpatient and child guidance clinics, where they have been found to account for 14% and 9% of attenders (Srinath *et al.*, 1993; Chaudhuri *et al.*, 2007), rates being even higher among inpatients (30% in Srinath *et al.* (1993)). Conversion disorders constituted 2–8% of children observed by a Turkish clinical child psychiatric service (Pehlivanurk & Una, 2008).

These comparatively high rates have been thought to be related to Asian cultures being more reserved in expressing feelings and distress and by requests for medical attention for bodily symptoms being more imperative than purely psychological ones. However, the rates have been derived from clinical samples and we are not aware of systematic studies that examine the influence of culture and ethnicity on the aetiopathogenesis of various somatoform and related disorders in children.

Longitudinal outcome and long-term adjustment

Short-term surveys of, for the most part, clinical samples of children with somatoform disorders show that the majority recover in the short run, although some continue to experience symptoms of lesser severity and/or develop psychiatric disorders. For example in highly “somatizing” adolescents, a 4-year follow-up documented an enhanced risk for major depression and panic attacks (Zwaigenbaum *et al.*, 1999).

The majority of long-term prospective outcome studies have addressed general population samples or young people with abdominal pains attending specialist services. These data are consistent in showing that somatic symptoms predict in adulthood somatic symptoms, but also psychiatric comorbidities including depression and anxiety (Hotopf *et al.*, 1998; Hotopf *et al.*, 1999; Dhossche *et al.*, 2001; Fearon & Hotopf, 2001; Steinhausen & Winkler, 2007; Shelby *et al.*, 2013).

The existing literature indicates that childhood FSS, conversion disorder and CFS will rarely be the forerunners of medical disorders, but whether this is the case in clinical practice may depend on the thoroughness of the medical assessments, and it is worth noting that some studies have excluded from follow-up children with subsequent medical problems (Shelby *et al.*, 2013).

The following sections describe outcome in clinical populations with different somatoform and related disorders.

Abdominal pains and other pain syndromes

It is rare for children with recurrent abdominal pains seen in specialist clinics to develop an explanatory organic disorder at follow-up (1 out of 31 former patients in Walker (1995)). Nevertheless, symptom persistence is observed in a substantial minority. Longer term follow-up studies have reported persistence of abdominal pain into adulthood in up to one half of affected children (Apley & Hale, 1973; Christensen & Mortensen, 1975) and links with both adult psychological comorbidity—mainly depression and anxiety (Shelby *et al.*, 2013)—and somatic complaints, including other chronic pain conditions and headache (Walker, 1995, 2010). Impairment and coping mechanisms are relevant to outcome. In a 9-year follow-up of children with RAP, the risk of persistence of chronic pain and of psychiatric disorders was doubled in the quarter of children with a “dysfunctional high pain profile” characterized by low perceived pain coping and efficacy, high levels of negative affect, pain catastrophizing and functional

disability when compared with patients with adaptive pain profiles (Walker *et al.*, 2012).

A 3-year follow-up of adolescents with fibromyalgia revealed persistent symptoms in close to two-thirds as well as significantly more symptoms of anxiety and depression compared with healthy controls (Kashikar-Zuck *et al.*, 2010).

Chronic fatigue syndrome

Although about two-thirds of children with CFS attending specialist services may be expected to recover, this can be protracted, a 3-year follow-up documenting a mean time to recovery of 38 months (Rangel *et al.*, 2000b). Moreover, even after recovery, half of the young people remained prone to fatigue, and nearly two-thirds developed a psychiatric disorder mainly consisting of anxiety disorders (Garraalda *et al.*, 1999). In a longer term follow-up of young people with CFS-like illness, a third of the patients considered themselves recovered, the rest being either not fully recovered or chronically ill (18%) (Bell *et al.*, 2001).

Conversion disorder

Follow-up studies of children and young people with conversion disorders note clinical improvement in 56% to 100% (Pehlivanurk & Unal, 2002; Ani *et al.*, 2013). Many cases appear to recover within 3 months and some symptoms remit spontaneously or with minimal intervention after a few days or weeks. In a Turkish 4-year follow-up study (Pehlivanurk & Unal, 2002), complete recovery was reported in 85% and favourable outcome was predicted by early diagnosis and good premorbid adjustment. However, 35% developed a new psychiatric disorder during follow-up, especially anxiety and depressive disorders.

Risk factors

Although the aetiology of FSS and somatoform disorders remains incompletely understood, most investigators agree on multifactorial influences whereby an interplay of genetic and environmental factors shapes the development and perpetuation of symptoms. A biopsychosocial model is the preferred current operational framework for FSS and somatoform disorders, as it recognizes the interaction between physiological and psychological processes with social and environmental influences.

In clinical practice, a complex explanatory model for the development and maintenance of FSS and somatoform and related disorders can be used, which takes into account the various risk factors and typically subdivides them into *vulnerability* (the person's susceptibility to develop the disease), *precipitants* or *triggers* (factors that directly cause the onset of the disease) and *maintaining*, which maintain or aggravate the pathological processes (Figure 72.2).

Various aetiological and pathophysiological factors may be relevant at different times in this process and it rarely makes sense to talk about “the cause”.

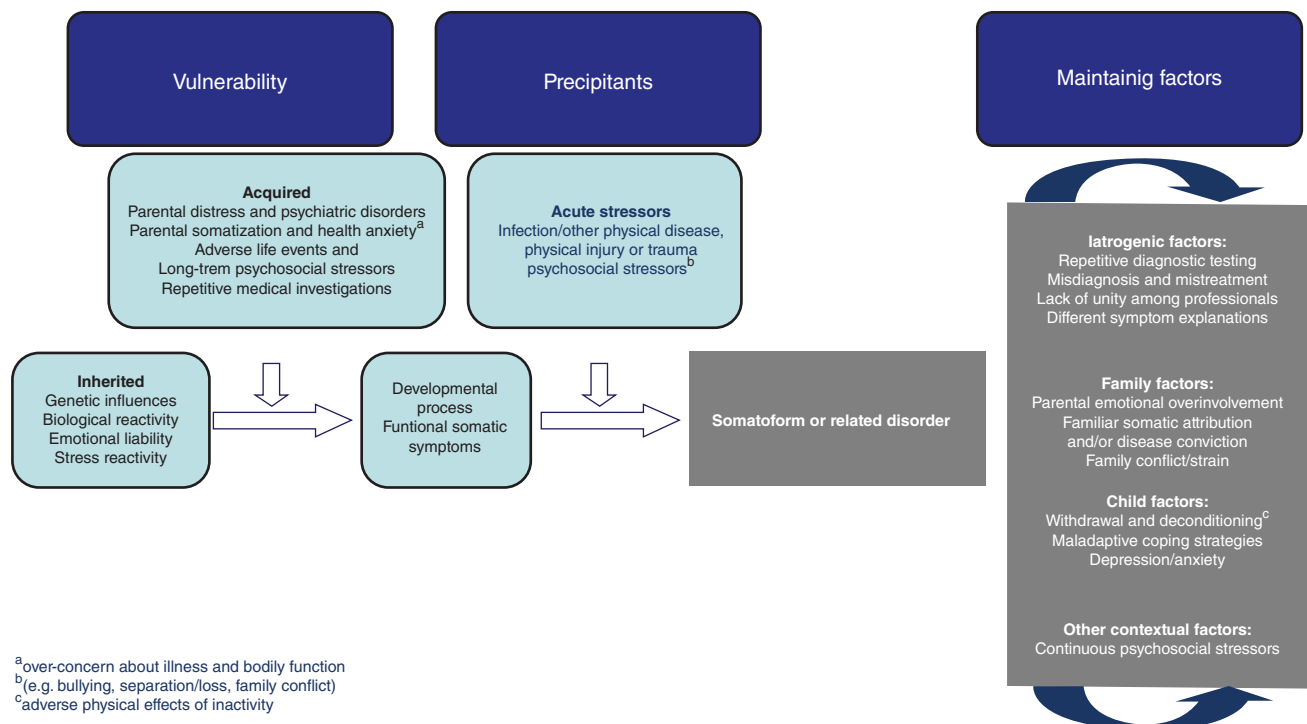

Figure 72.2 Explanatory model. Explanatory model for the development and maintenance of functional somatic symptoms and somatoform and related disorders.

Although vulnerability and maintaining factors have a central aetiological role, the triggers determine *which* symptoms develop and as a result, the child and family may consider them to be the “cause”. These are often somatic in nature, for example, an infectious illness commonly precipitates pediatric CFS (Garalda & Rangel, 2002). In conversion disorder, a problem in walking may be triggered by a broken leg and pseudo-seizures coexist with epilepsy, but antecedent stressors are also reported for 80%, most commonly bullying in school, separation and loss or family conflict or violence (Kozłowska *et al.*, 2007; Ani *et al.*, 2013).

While vulnerability factors will influence the development of a syndrome, treatment most usefully addresses maintaining factors susceptible to change. Nevertheless, the same factors may be both predisposing and maintaining, and as the existing empirical evidence tends to be based on cross-sectional studies and cannot differentiate cause and effect, in the following sections we will consider joint vulnerability and maintaining factors, divided according to their biological or psychosocial nature.

Biological factors

Familial clustering is well established in the literature on somatoform disorders and functional somatic syndromes such as IBS and CFS (Wright & Beverley, 1998; Garalda, 2000; Craig *et al.*, 2002; Levy *et al.*, 2004; Crawley & Smith, 2007; Schulte & Petermann, 2011) and this is thought to reflect in part genetic influences. Twin studies have confirmed a genetic contribution to fatigue symptoms and CFS syndromes, although

genetic heritability appears to be stronger for short than for long duration of fatigue (Farmer *et al.*, 1999; Crawley & Smith, 2007). A joint action of genes and environment is assumed, but there is still insufficient clarity on the actual genes and environmental factors involved. Studies in adult patients have identified genetic influences interacting with environmental hazards in IBS, concordance being higher in monozygotic than in dizygotic twins (22% compared with 9%) heritability in females being estimated at 48% (Bengtson *et al.*, 2006).

There are indications that biological susceptibilities can influence the expression of somatoform syndromes. Children and young people with RAP report significantly greater symptom increase to a water load symptom provocation test than controls, suggesting gastrointestinal sensitivity (Walker *et al.*, 2006a). To explain the high levels of comorbidity between abdominal pains and mood disorders, and given that serotonin is an important neurotransmitter in the gastrointestinal tract and enteric nervous system, Campo *et al.* (2003) have put forward the possibility of dysregulation of serotonergic neurotransmission as being implicated in both, although this is an issue requiring empirical validation.

As pain somatoform disorders when severe usually involve pain in different bodily sites, it is possible that central pain sensitization is a contributing factor, as a result of elevated responsiveness to nociceptive stimuli resulting from increased spinal cord neuron excitability, but this again needs more empirical confirmation (Al-Chaer *et al.*, 2000; Mayer & Collins, 2002; Walker *et al.*, 2012).

The increased stress reactivity and emotional lability associated with child somatoform disorders discussed in the following sections point to a possible role of the hypothalamic–pituitary–adrenal system. Significant associations between cortisol levels and clusters of FSS have been identified: an overtiredness and musculoskeletal pain cluster being associated with low cortisol after awakening, and a gastrointestinal and headache symptom cluster being associated with low cortisol levels during psychosocial stress (Janssens *et al.*, 2012).

There have been reports of autonomic dysregulation—with high blood pressure and heart rate at rest and orthostatic anomalies—in pediatric CFS (Wyller *et al.*, 2007, 2008), but it is difficult to know the extent to which this is primary or secondary to the sometimes profound “physical deconditioning” resulting from prolonged inactivity. Children with functional abdominal pains fail to report the expected higher pain threshold in the presence of elevated blood pressure when compared with healthy controls, which may possibly reflect autonomic dysregulation or its interplay with overlapping systems modulating pain (Bruehl *et al.*, 2010).

Psychosocial risk factors

Psychosocial risk factors can be subdivided into child psychological features, factors in the family, and in the school or wider environment, including adverse life events, all of these acting as both vulnerability and maintaining the symptoms and impairment.

Child factors

Psychological features in the child known to be associated with the development and maintenance of FSS or somatoform symptoms include early reactivity, vulnerable personalities and ineffective coping styles. A consistent finding is the very high co-morbidity with anxiety and mood disorders, suggestive of shared underlying risks.

Personality and temperament

There have long been pediatric observations of children with RAP having characteristic personalities, such as conformism and obvious attempts to please adults and obtain approval, sensitivity to distress and insecurity, anticipation of dangers and failures for themselves and their families (Garraalda, 1992b). Davison *et al.* (1986) described an excess of irregular temperamental styles and a tendency to withdraw in new situations in young primary school children with abdominal pains when contrasted with healthy controls, and work on young people with CFS has identified high rates of personality disorder and difficulty characterized by conscientiousness, vulnerability, worthlessness and emotional lability when compared with healthy controls or with children with other chronic pediatric disorders such as juvenile arthritis (Rangel *et al.*, 2000a). These traits are comparable to personality features of young people with anxiety and mood disorders (Rangel *et al.*, 2003), suggesting shared vulnerabilities.

Their precursors may manifest in infancy through hypersensitivity to sensory and tactile stimulation and difficulty in self-regulation, as two studies have now found this to predict the development of recurrent somatic and impairing symptoms in later childhood (Ramchandani *et al.*, 2006; Rask *et al.*, 2013b).

Stress reactivity and coping mechanisms

Temperamental and personality features may underlie enhanced stress reactivity in children with impairing somatic symptoms. Those with recurrent abdominal pains report more daily hassles and stressors both at home and in school than normal children and a stronger association between daily stressors and somatic symptoms (Walker, 2001). They also appear to be less confident in their ability to change or adapt to stress and less likely to use accommodative coping strategies (Walker *et al.*, 2007). Empirical evidence from studies in children with headache and abdominal pain further supports the notion that children with high levels of somatic symptoms tend to use poor coping strategies characterized by negative affect and avoidance (Walker *et al.*, 2012). Young people with CFS report higher levels of distress about their condition than controls with other pediatric chronic conditions and less use of active problem solving techniques when dealing with illness and impairment (Garraalda & Rangel, 2004).

The adult literature has addressed the possible role of other psychological mechanisms for the development of FSS, such as alexithymia (i.e. difficulties identifying feelings and differentiating them from bodily arousal), dissociation (or failure to integrate different elements of consciousness), introspection, the somatosensory amplification of physical sensations and anomalous illness attributions. Results, however, have not been conclusive (Duddu *et al.*, 2006) and these mechanisms have been comparatively little explored in children.

Family factors

Parental and family influences are highly relevant. Mothers of children with recurrent abdominal pain have an excess of histories of anxiety and depression (Campo *et al.*, 2007), and parental anxiety and psychiatric disorder during the child's first year of life predict FSS in children 6 years later (Ramchandani *et al.*, 2006; Rask *et al.*, 2013b). Children of parents with current somatization display an excess of somatic symptoms and school absence (Craig *et al.*, 2002).

Of more immediate relevance, a particularly high parental focus and involvement with the child's somatic symptoms are associated with the development of FSS in young people. Work with children with recurrent abdominal pains has shown that parental behaviours that entail giving attention to the symptom result in doubling of complaints, especially in girls, whereas distraction reduces the symptoms by half. Interestingly, while children in these experiments report that distraction makes the symptoms better, parents rate distraction to be more likely than attention to have a negative impact on their children's symptoms (Walker *et al.*, 2006b). These findings may reflect high levels

of “accommodation” of the family to the child’s symptoms, similar to that described in children with emotional disorders (Lebowitz *et al.*, 2013).

Work on young people with CFS has demonstrated high levels of parental emotional over-involvement with the children’s illness, when compared with parents of children with other chronic pediatric disorders (Rangel *et al.*, 2005). Over-involvement is manifested at interview by parental comments that include overprotectiveness and self-sacrificing behaviours as well as preoccupation with the child, which are over and above what may be expected from the child’s age and developmental level, melodramatic speech, intense affect and preoccupation with the past. In addition to parental “disease conviction” or over emphasis on possible medical causes for the symptoms despite negative medical investigations, such parental attitudes may impede adolescents in developing active coping mechanisms. Conversely, parental acceptance of a multifactorial illness model can be associated with a better prognosis (Crushell *et al.*, 2003).

Social factors

Epidemiological work on children with somatic symptoms has found associations with broad psychosocial stressors such as broken families—although the latter is not necessarily associated with symptom-related impairment—and with preceding or contemporary negative life stresses or events (Aro, 1987; Boey & Goh, 2001; Vila *et al.*, 2012). Stressful events are reported as illness precipitants in the majority of clinical studies of children with conversion disorder (Ani *et al.*, 2013). Examples of emotional and social stressors may be the loss of a close family member, parents’ divorce, but school events such as pressure on the child to perform in school or being bullied are especially reported. Studies in adults with somatoform disorders have documented an excess of sexual abuse and disruptive early life experiences but the evidence on sexual abuse is somewhat inconclusive (Chen *et al.*, 2010) and these factors have not emerged as of general significance in the child literature.

In addition to familial and school factors, the health system itself can become iatrogenic. Physicians tend to pursue organic explanations and repeated medical investigations, which can lead to amplification of the children and family’s illness worry and behaviour. In a study of young people with CFS observed in specialist clinics, a mean of seven medical professionals had already been consulted (Rangel *et al.*, 2000b) and repeated medical assessments are also a feature in non-transient conversion disorders (Ani *et al.*, 2013). This has to be tempered against the danger of under-investigating and missing a primary medical disorder and clearly any organically suspicious symptom should promote a reassessment of possible medical causes. However, it is important to note that the diagnosis of a somatoform disorder should be made positively on the basis of the characteristic psychological features and that a somatoform disorder may indeed coexist with a medical problem (Garralda, 1992b).

Pathological risk processes

The biological and psychosocial factors described earlier may in combination be expected to influence the development and maintenance of somatoform and related disorders. In explaining the processes through which they exert their influence, it is useful to consider the role of impairment.

Functional impairment involves withdrawal from everyday responsibilities and stresses. As outlined under risk factors, children with somatoform disorders are described as stress sensitive; they therefore find themselves comparatively frequently in situations that are unsettling and upsetting, which they find difficult to manage. In this context, illness—despite being an unpleasant and distressing physical experience—represents a welcome escape from stress. It provides the child with a source of control over the rate at which ordinary life and its attendant stresses will be confronted and managed. This could explain why some children appear to “hold on” to the illness and oppose or resist rehabilitation attempts and expectations from others.

Childhood somatization has been further articulated in terms of superficially compliant children who tend to avoid overt expressions of vulnerability or distress, but who find themselves in intolerable “predicaments” they cannot escape or communicate, without threatening their feeling of safety. Physical illness would serve to elicit parental care and protection and safeguard the child from parental expectations and anger, displeasure or rejection in the face of failure to perform (Kozłowska, 2001).

Assessment. Treatment and treatment setting

Assessment using a biopsychosocial framework

The assessment of young children relies primarily on parental information and child/parent interactions, while in older children more emphasis will be put on interviews with children. Dual assessments are important given the limited concordance in symptom reporting in parents and children (Garber *et al.*, 1998).

Core assessment includes in the first place a detailed medical and psychiatric history and examination, together with a thorough review of previous medical records; secondly, the assessment of physical and psychiatric comorbidity; and thirdly, the use of a biopsychosocial perspective that takes into account biological, psychological and social risk and maintaining factors, which will be central to the rehabilitation process.

The assessment needs to take into account the medical disorders that are being investigated alongside the mental health referral and maintain a physical/medical or a psychiatric/psychosocial perspective, which may include liaison and discussion with pediatricians or other medical teams. Contact with schools and especially clarification of school absence and of other potential educational and social problems is important. Standardized questionnaires and interviews that may be helpful in the assessment are summarized in Table 72.3.

Table 72.3 Selected measures for assessment of functional somatic symptoms and somatoform and related disorders.

Rating scales Measure (Ages)	Domaine	Time frame/scale	Versions	Comments
Children's Somatization Inventory (CSI) [8–18 yrs] (Garber <i>et al.</i> , 1991; Walker, 2009)	Somatization	Past 2 weeks 5-point scale: bothered <i>not at all</i> to a <i>whole lot</i> (score 0–140)	Child, parent version Original version (35 items) Short version (18 items) Revised version (24 items)	Subscales of pseudoneurological, cardiovascular, gastrointestinal and pain/weakness symptoms akin to somatization disorder symptom categories In the revised version, CSI-24, statistically weak items have been removed, making it more appropriate for children and adolescents
Childhood Illness Attitude Scales (CIAS) [8–15 yrs] (Wright and Asmundson, 2003)	Health anxiety	Not stated 3-point scale: Applies: <i>none, some or a lot</i> (score 33–99)	Self report (35 items)	Covers fears, beliefs and attitudes associated with hypochondriasis and abnormal illness behaviour and parents'/guardians' role in facilitating medical attention or treatment Questions regarding recent medical treatment less reliable and probably need revision. Measures physical and mental fatigue in CFS patients
Chalder Fatigue Scale (CFS) [10 yrs+] (Chalder <i>et al.</i> , 1993)	Fatigue	Not stated 4-point scale (0, 0, 1, 1): Applies: <i>less, no more, more, much more than usual</i> (score 0–11)	Self report (11 items) Score 0–11	
Functional Disability Inventory (FDI) [8–18 yrs] (Walker <i>et al.</i> , 1991)	Impairment/physical functioning	Past 2 weeks 5-point scale: No problems to (score 0–60)	Child, parent version (15 items)	Has primarily been used to assess physical disability in a variety of pediatric chronic pain conditions such as abdominal pain, fibromyalgia, headaches, back pain and other non-disease specific musculoskeletal pain syndromes
Interview modules				
Interview [Ages]	Diagnoses	Time frame/interview type	Versions	Comments
Munich-Composite International Diagnostic Interview (M-CIDI) [Adult interview applied in children and adolescents with age as low as 12 yrs] (Wittchen <i>et al.</i> , 1998)	Somatoform and dissociative disorders including subtypes	Life time Highly structured interview	Self report No parent version	Includes 46 symptoms according to DSM-IV/ICD-10 Probably not applicable to younger children
Schedules for Clinical Assessment in Neuropsychiatry (SCAN) [Adult interview applied in adolescents] (Brugha <i>et al.</i> , 2001)	Somatoform and dissociative disorders including subtypes	Current /previous/life time Semi-structured interview	Self report No parent version	Includes 78 symptoms according to DSM-IV/ICD-10 Probably not applicable to younger children

(continued)

Table 72.3 (continued)

Interview modules Interview [Ages]	Diagnoses	Time frame/interview type	Versions	Comments
The Child and Adolescent Psychiatric Assessment (CAPA) [9–17 yrs] & The Preschool Age Psychiatric Assessment (PAPA) [3–6 yrs] (Angold <i>et al.</i> , 1995 and Egger & Angold, 2004)	Symptom diagnosis based on information on onset date, duration, frequency and impact	Past 3 months Interviewer-and glossary-based interview	CAPA: child/parent version PAPA: parent version	Includes only three symptoms: headache, stomach ache and musculoskeletal pain
The Soma Assessment Interview (SAI) [5–10 yrs] (Rask <i>et al.</i> , 2009a)	Functional somatic symptoms, –/+impairment	Past year Mixture of highly structured and open-ended questions. Final assessment by a clinical rater	Parent version No child version	Consists of 5 sections covering items on the child's: (i) physical health, (ii) physical complaints, (iii) duration and impact of possible unexplained somatic symptoms, and number of doctor's visits during the past year due to these symptoms and (iv) health anxiety symptoms Probably not applicable to older children and adolescents

Treatment setting

The management should ideally follow a stepped care mode according to the level of specialization required by each patient (Figure 72.3).

Most children with FSS are seen by primary health care practitioners and pediatricians and improve with medical examination, explanation and advice built on psycho-educative principles. In pediatric settings, parents of children with FSS, especially mothers with high anxiety levels, provide more positive feedback to biopsychosocial than to purely biomedical pediatric consultations (Williams *et al.*, 2009). This accords with the fact that many mothers of children consulting for abdominal pains, and indeed with conversion disorder, acknowledge a contribution of psychosocial factors to their children's symptoms (Claar & Walker, 1999; Ani *et al.*, 2013).

The cornerstone of treatment is for pediatric clinicians to be interested in the child and its background, to carry out the necessary investigations, to discuss with parents tactfully that organic disease has been excluded and any harmful aspects in the child's environment (such as excessive academic and emotional demands, often self-imposed by the child) and to help modify them. Sharing information about the population frequency of FSS, existing knowledge about risk factors as well as guidance about management strategies can be helpful in "normalizing" the problem and "empowering" families in management.

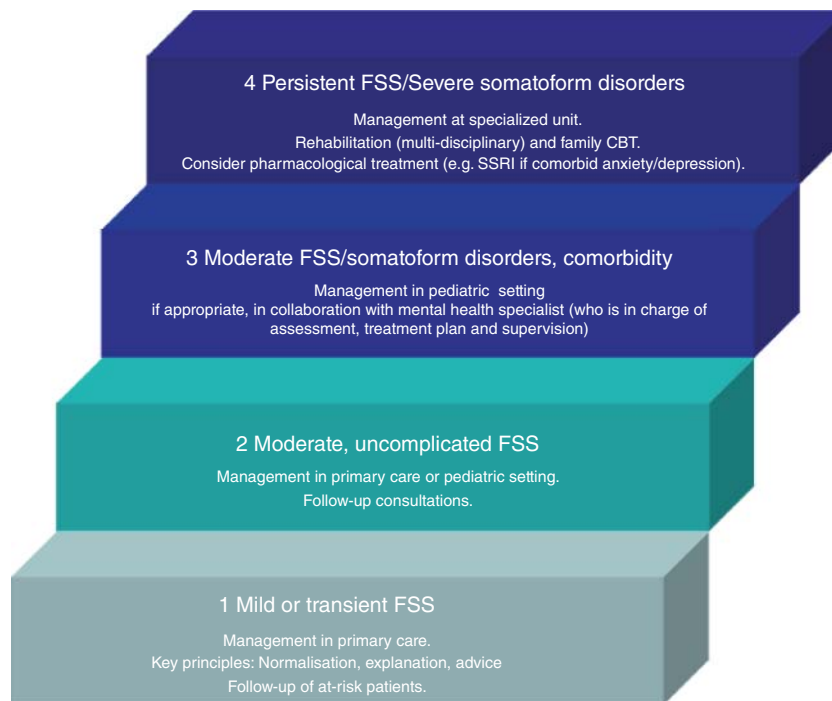

More specific advice may involve (i) pain management with the use—as appropriate—of relaxation (especially for headaches) and distraction techniques, combined with negotiated reduction of avoidance and inactivity and graded return to school if applicable; (ii) addressing contributory factors such as stresses in school or from peer interactions, helping parents decrease their concerned attention to symptoms, while increasing attention and encouragement of non-pain behaviour and shared enjoyable activities.

For children with more protracted problems, the referral from pediatrics to child mental health services requires a sensitive appreciation by all concerned of the "somatic focus" and reluctance to accept a mental health approach by a number of children and families. Details on how this may be achieved are given in Table 72.4.

Comorbid mood disorders will require specific and coordinated treatment as will comorbid medical disorders. Severe cases and pervasive withdrawal may call for inpatient treatment, a multidisciplinary and often multiagency approach with school involvement.

Specialized mental health treatment

To become involved with psychological treatments, children and parents need to perceive that the somatic symptoms and their predicament are taken seriously by clinicians, that their concerns are not dismissed as being "all in the mind" or "all in the family"

FSS: functional somatic symptoms

Figure 72.3 Stepped care model for the management of functional somatic symptoms and somatoform and related disorders. *Source:* Inspired by model presented in Schroder and Fink (2011).

Table 72.4 General principles for helping engagement in assessment and treatment (Goldberg *et al.*, 1989).

Stage 1 Feeling understood
Take a full history of the child's symptoms
Explore emotional cues
Explore social and family factors
Explore the families health beliefs/illness perception
Brief focused physical examination if indicated
Stage 2 Broadening the agenda
Feedback the results of the examination
Acknowledge the reality of the symptoms and related impairment
Reframe the complaints in a biopsychosocial model: link physical, psychological and social factors
Stage 3 Making the link
Give a simple explanation
<ul style="list-style-type: none"> How stress, tension and anxiety cause or aggravate physical symptoms How depression lowers the pain threshold
Demonstrate
<ul style="list-style-type: none"> Practical (e.g. how pain results from tense muscles) Link to life events (e.g. how pain can be made worse by stressors) "Here and now" (e.g. rate the pain and link to feelings)
Broaden the scope (ask if anyone else in the family or among friends has suffered from similar symptoms)

Source: Adapted from Elsevier.

and that the rehabilitation approach will be collaborative and proceed *at a pace* that the child and family can manage and is acceptable to them.

In line with the guidelines described earlier, psychological treatment approaches will best involve psycho education and exploration of concerns and illness beliefs and be followed by symptomatic treatment, with an emphasis on rehabilitation and learning to cope with symptoms, alongside the exploration and management of contributory stressors (often involving problems in school and in peer relationships) and/or psychiatric disorders. Because of the importance of parental influences, family work is of the essence.

The best evidence of efficacy comes from randomized controlled treatments (RCTs) using relaxation for circumscribed problems such as headaches and family-based cognitive behavioural therapy (CBT). Additional treatments showing promise are hypnotherapy and new cognitive behavioural therapies such as Acceptance Commitment Therapy (ACT) and mindfulness techniques.

Specific cognitive-behavioural techniques involve self-monitoring of the main symptoms through diaries, teaching children to observe symptom fluctuation with changes in intensity and severity, limiting the attention given to the symptom by others, relaxation if appropriate and encouraging participation in routine activities through gradual exposure,

Table 72.5 General principles for the treatment of somatoform and related disorders.

-
- **Goal setting:** establish realistic goals with a good chance of success in the light of the child's illness and the framework of the therapy
 - **Engagement and motivation:** provide the rationale for a treatment programme emphasizing the focus on reducing impairment
 - **Psycho education:** including (i) the body's reaction to stress and how stress may be expressed in somatic symptoms, (ii) possible biological and physiological basis for the symptoms, and (iii) sleep hygiene and dietary advice
 - **Links between symptoms and stress:** use diaries for documentation of variations in symptom intensity in relation to stressors in everyday life, which may provide a focus for intervention
 - **Behaviour:** address dysfunctional avoidance behaviour, e.g. increasing school absence
 - **Coping:** help the child and family learn new techniques to cope with specific symptoms and impairments e.g. distraction, muscular relaxation for headaches, graded physical exercise for muscular problems and fatigue, practical management of pseudo-seizures
 - **Family and social network:** address any factors in the family or school that may be contributing to the symptoms or interfering with symptom resolution
 - **Address help-seeking behaviour:** gradually shift the burden of responsibility from clinician to parent/patient
 - **Treatment of comorbid psychiatric problems**
 - **Consider psychopharmacologic interventions:** especially for comorbid internalizing disorders such as anxiety and depression
 - **Establish joint professional meetings** and integrated investigations and management plans between different medical and other professionals involved
-

while confirming that the child is not feigning the symptom. Key principles of treatment are provided in Table 72.5.

The following sections describe in more detail treatment options for different somatoform and related disorders.

Treatment of recurrent abdominal pains

There is now evidence supported by randomized controlled trials (RCTs) that family CBT programmes can be efficacious for RAP. An early RCT by Sanders and colleagues (Sanders *et al.*, 1994) showed this to be superior to treatment as usual and was replicated by Robins and colleagues (Robins *et al.*, 2005). The main ingredients of Sanders *et al.*'s active CBT intervention were: (i) discussion of investigations and of the rationale for pain management; (ii) reinforcement of well behaviour by promotion of distracting activities, ignoring non verbal pain behaviours, avoiding modelling the sick-role and discriminating the seriousness of symptoms; (iii) promoting coping skills such as relaxation, positive self-talk and distraction; (iv) problem solving for future pain involving positive imagery skills. In this study, over 50% of children were pain free on children's diaries at the end of active treatment compared with approximately 20% who had standard pediatric treatment (70% compared with about 30% according to parental reports) and the gains were largely maintained at 6- and 12-month follow-up. Levy *et al.* with a much larger sample of 200 children compared three

sessions of CBT (aimed at altering parental responses to pain as well as children's coping responses to it) with three educational sessions. CBT was associated with significantly greater decrease in pain and gastrointestinal symptom severity and in parental solicitous responses to pain, and the effects were maintained at 12-month follow-up (Levy *et al.*, 2010).

A meta-analysis has confirmed the effectiveness of psychological therapies, principally CBT (in person and on line) and relaxation in the treatment of children with chronic abdominal pain (Sprenger *et al.*, 2011). Hypnotherapy can also help reduce abdominal pain intensity, although the existing evidence makes it difficult to quantify the exact benefits (Vlieger *et al.*, 2007; Rutten *et al.*, 2013). There is little evidence of efficacy of biological/medical or dietary treatments (Huertas-Ceballos *et al.*, 2002; Horvath *et al.*, 2012; Wright *et al.*, 2013).

Treatment of headaches

National Institute for Health and Care Excellence (NICE) guidelines (2012) advise the use of paracetamol or NSAIDs (non-steroid anti-inflammatory drugs) during the acute phase of tension-type headaches in young people and adults, but preparations containing aspirin are contraindicated under 16 years because of the association with Reye's syndrome (Carville *et al.*, 2012). However, ongoing use of painkillers is not recommended and alarm has been caused by reports of a marked increase in the use of paracetamol over recent decades by children and adolescents, alongside an increase in the number of children reporting stomach aches (Holstein *et al.*, 2009).

A variety of drug treatments are recommended for the treatment and prophylaxis of pediatric migraine (Lewis *et al.*, 2002). Nevertheless, it is also recognized that behavioural treatments such as relaxation training, biofeedback, CBT and stress-management training can be superior to placebo in the treatment of both tension and migrainous headaches (Rains *et al.*, 2013).

Treatment of juvenile fibromyalgia and other pain syndromes

CBT strategies have also been found effective for the treatment of fibromyalgia. An RCT reported this to significantly improve function compared with controls assigned to only self-monitoring (Kashikar-Zuck *et al.*, 2005).

Acceptance and Commitment Therapy (ACT), an extension of traditional CBT with a focus on improving functioning and quality of life, has recently been developed for the treatment of children with pain syndromes. This promotes acceptance of negative reactions (thoughts, emotions and bodily sensations) of pain and other symptoms that cannot be directly changed, and the promotion instead of activities that are meaningful to the patient, even if painful or fear-provoking, as a means of helping patients distance themselves from the pain or distress. A recent small RCT of children with longstanding pain showed ten

weekly sessions to be significantly superior to usual treatment including Amitryptiline, in terms of functional disability, pain intensity and discomfort (Wicksell *et al.*, 2009).

Treatment of chronic fatigue syndrome

A rehabilitation treatment framework offers most chances of success. Understanding the maintaining power of inactivity for fatigue and the related behavioural vicious circles that follow from this can be helpful, fatigue leading to inactivity which in turns generates more fatigue. A behavioural family approach will address this through a graded activity program while acknowledging fear that activity may make the condition worse, a belief often based on unsuccessful previous attempts to fight the symptoms (Garralda & Rangel, 2005).

This approach is broadly supported by the existing research evidence. A pilot RCT found active rehabilitation to be superior to patients "pacing" themselves by acting according to their subjective tiredness and energy levels (Wright *et al.*, 2005) and in an open study of young people with CFS, those taking part in an active treatment programme performed better than those declining involvement (Viner *et al.*, 2004). RCTs have shown CBT to be superior to waiting list controls (Stulemeijer *et al.*, 2005; Knoop *et al.*, 2008), although its superiority over psycho education is less clear-cut (Chalder *et al.*, 2010). CBT can be successfully delivered through Internet-based interventions and this has been found to be more efficacious than standard care (Nijhof *et al.*, 2012). NICE guidelines emphasize the importance of family engagement and of establishing a supportive and collaborative relationship with the child and family (Baker & Shaw, 2007). Good communication is regarded as essential, supported by evidence-based information to allow families to reach informed decisions about the child's care. Generally, it is recommended that CBT and/or graded exercise therapy should be offered because currently these are the interventions for which there is the clearest research evidence of benefit.

Treatment of conversion disorder

Probably because of its rarity, there are no trial-based evidence treatments for childhood conversion disorder. Descriptions of useful treatments include graded physiotherapy programmes (Brazier & Venning, 1997) and these are to be recommended alongside the general principles for the treatment of other somatoform-like disorders.

Medication

Selective serotonin reuptake inhibitors (SSRIs) such as Citalopram have been piloted successfully for the treatment of RAP but there is not as yet direct evidence of efficacy (Campo *et al.*, 2004b). In adults, antidepressants have been found to have a moderate to good effect in the treatment of different types of functional somatic syndromes (Henningsen *et al.*, 2007).

Treatment of psychiatric comorbidity

The most common psychiatric comorbidities and their treatment will follow the guidance provided in the relevant *chapters in this book*.

Treatment of severe withdrawal cases

For the treatment of severe cases of pervasive withdrawal, a coordinated multidisciplinary rehabilitation package is required that ensures consistency and collaboration between different professionals and families. This will commonly involve attending to basic needs with assisted feeding and elimination, exposure to a selected group of carers, gentle encouragement to communicate verbally, active treatment of any comorbid anxiety or depressive disorders and family work. Any parental misgivings about treatment need to be addressed and progress must be expected to be slow at early stages until the child's mood and trust in therapy improve to the extent of allowing them to start "letting go" of their withdrawal (Nunn *et al.*, 1998).

Cultural aspects with regard to treatment

In traditional cultures, patients with conversion disorders are sometimes managed by traditional healers and methods such as carrying charms, visits to tombs of religious figures or sacrificing animals have been described (Pehlivanturk & Una, 2008). In Western countries, herbal and alternative medical treatments are commonly used for somatoform-like disorders (Rangel *et al.*, 2000b), but—as for the traditional healer procedures—there is no evidence of efficacy.

Future developments and necessary research

Further research may usefully approach the study of aetiological factors and pathological processes, including early risk factors and gene-environmental interactions, through neuroimaging and prospective epidemiological studies. This may begin to elucidate why some children with early stress reactivity or those exposed to negative life events develop FSS and other depressive illness, while others remain healthy. Developmental neurogenomics may provide the direct link to further our understanding of how biological, psychological and social processes interact over a lifetime to influence health and susceptibility for the development of somatoform and related disorders. It will be of interest to investigate further attitudinal aspects, such as the contribution of illness perceptions and health anxiety in the child and family for the maintenance of somatoform symptoms. Moreover, there is a high need for the further development and evaluation of evidence-based treatments. Future work needs to address the relative cost-effectiveness of early preventative interventions alongside that of pediatric liaison and mental health treatments for children with somatoform disorders, across different cultures and health service organizations.
